GOVERNMENT AND LAWS.

I.—GOVERNMENT.

Formal constitution.

"BY the constitution of a country, is meant so much of its law as relates to the designation and form of the legislature; the rights and functions of the several parts of the legislative body; the construction, office, and jurisdiction of courts of justice." This is the definition given by Paley. It seems necessary to add also, "whatever prerogatives are vested in the executive;" at least, in case any powers and privileges are conferred on it beyond what, from being indispensable to the administration of the public affairs of a community, must be common alike to all executives. Even with this addition, the mere mechanism of a government, in the three principal relations which it bears to its subjects, is all that is here described. Yet something more is generally understood by a constitution, and would seem to be properly comprehended under that name. A government, it is true, may and must be influenced in a hundred ways by independent circumstances, and by manifold considerations, which are no part of it. But when certain specific tendencies and principles are directly and designedly moulded into its original conformation as so many distinct ends and maxims, or when they are subsequently developed by it or incorporated with it, so as to guide and qualify its spirit, they become entitled to the character of constitutional as much as the organization itself. There is no doubt that the mechanism of a government, if left to itself, will mainly determine the nature and direction of its movements; yet this mechanism consists of a moral and intellectual agency. It is accordingly capable of accommodating itself, and of working in subjection to whatever rules and impulses may be impressed upon it by the society whose instrument it is.

No society can be so stationary but that changes must take place, sooner or later, for the better or for the worse, in some one or other of the conditions, whether of principle or of organization, which make up its constitution. When these happen to take place, hardly any society can have been so judiciously constructed from the first, or be so fortunate in all its future circumstances, that lawyers shall be able at once to call every change which is for the worse, unconstitutional, and which is for the better, constitutional. An approximation to this favourable situation has been one of the great and innumerable advantages of the uniform and gradual progress by which the English constitution has been distinguished. Its history is the history of the internal policy of a people, who at every advance in civilization succeeded in occupying one advanced post after another, fortifying their free position at every remove. The early prospect would have discouraged the most sanguine philosopher. But the evil tendencies were suppressed, and the good ones brought forward, until the process appears to resemble the natural development by which a germ grows up into a plant, with but little occasional help from the pruning hand of man. Precisely the reverse might have happened. It is what takes place during that imperceptible decay, which, by a foolish analogy to vegetable and animal life, it has been supposed that institutions are also destined to undergo. The bulk of mankind more easily perceive that abrupt and extensive changes, the innovations by which new principles, or a new organization, are introduced, amount in fact, as far as they go, to a new constitution. This may be done legally or illegally. If illegally, it is a revolution; a case which by the supposition has nothing to do with law. If legally, the letter of the law and the forms of the

---

Government and Laws.

constitution may be used for the purpose of substituting a worse as well as a better government to the extent that the ancient constitution is displaced. The question, what name will most properly describe any specific measure of this class? must depend upon the nature and degree of the measure. There is on these occasions another question for a people, prior in time, and far more important than discussions about a name. It is their duty to ascertain whether the proposed change is, under all the circumstances, a practicable improvement, and to fix where the authority for deciding this point can, upon the whole, be most safely lodged. A comparison of the different methods by which the latter problem can be solved will show what little cause there is for maintaining, as some modern writers are disposed to do, that the course adopted in England is too loose and arbitrary to be consistent with the positive character implied in a constitution.

Three very different systems may prevail in this respect. The two first are alluded to rather than recognised in English history. Its whole tenor proceeds upon the last.

Every country has at one time or another given more or less countenance, upon some favourite points, to the delusion of fundamental laws and unalienable rights; meaning by these, laws and rights incapable of alteration, except by a violence or decay equivalent to the suspension, if not dissolution, of society. Confounding the principle of moral and of legal obligation, Chief-Justice Hobart, from the bench, and Blackstone, calmly writing in his closet for the instruction of the eighteenth century, concur in stating that the supreme power of every state is necessarily subject to one condition. By this condition, all legislative commands against natural justice must be void in themselves, that is, void in law. With much less latitude than has often been given to the law of nature and to the rights of man, this exception might be made to cover extensive and dangerous ground. Lord Coke, for example, has said, that a statute against Magna Charta, or one to prevent the Irish from coming into England, would be void. In this manner the Stuarts were taught by servile judges to believe that most of the prerogatives anciently affixed to the crown were irrevocable even by act of parliament. A similar opinion, grounded on the doctrine of the three estates of the realm, was formerly propagated concerning the episcopal right of sharing in the legislature. At the Reformation, Bishop Gardiner conceived, that in consequence of the forced absence of himself and his brethren, its proceedings would be of none effect. The example was followed, but equally in vain, when, during the violent re-action provoked by Charles I., who considered himself as so pre-eminently a Church of England king, the bishops protested against all acts passed in their absence by a parliament no longer free. Charles I. held the very act by which the bishops were excluded, although some of them attended and voted against it, to be *ipso facto* null. The more intelligent a nation really becomes, the less likely is it thus to presume in favour of the political optimism of its own or of former times. No fiction can be more gratuitously mischievous than the creed that there can be any thing in the force of invading arms in 1066, or in the authority of national wisdom in 1688, or in any length of prescription whatsoever, to disable successive generations from exercising their own discretion respecting the propriety of their existing institutions.

Another plan is to set apart, in a written charter or declaration, certain excepted cases. The high matters which are the chosen objects of this deliberate sanction, are conceived to acquire thereby the privilege of being placed beyond the control of the ordinary legislature, and of being reserved for the direct volition of the body of the people. Locke, in treating of the right of popular resistance, seems to have stated too broadly, that the power of a community can never be exercised in this manner under any form of government, because such a proceeding, he says, presumes the government to be dissolved. Blackstone (vol. i. p. 161) expresses himself still more strongly to the same effect, adding, that no government will presuppose its own destruction. The contemplated occasions are neither as extreme in theory nor as impracticable in execution as this language would represent. There is really no question in this case about resistance, nor what can reasonably be called dissolution. Whilst, on the one hand, the law has nothing to do with possibilities belonging to the ultimate and latent right of resistance; on the other, the idea of a supreme power which may be lawfully resisted in points where it is called supreme, is of course a contradiction. Thus in an absolute government society must be remitted to its first principles before the right of popular interposition can be recognised by it. An ordinance of Louis XIV. declared that the extinction of the family of Bourbon would raise a case of this kind, and that on the occurrence of such event the right of electing to the crown of France would revert to the French people. But limited governments stand in an entirely different position. Minor contingencies, far short of the transgressions which justify an appeal to arms, or of the accident which summons a nation to the *Champ du Mars* to agree upon a successor to a vacant throne, are part of their necessities. The entire legislature may be only supreme *sub modo*. For under the doctrine both of fundamental laws and constitutional charters, every variety of restriction may be imposed upon the legislature. The prudence of these restrictions is more than problematical. But wherever a government consists of several parts possessing coordinate authority, the demand for some external control necessarily arises; since encroachments of one part on the other must be expected; and means ought to be arranged beforehand for bringing them back peaceably within their proper limits.

In this manner, wherever the doctrine of fundamental laws is admitted, a sufficient authority, as, for instance, a high court of justice, should be created for the purpose of inquiring into and correcting any violation of them with which the ordinary legislature may happen to be charged. It will be necessary, besides, to chalk out, as in primary assemblies or otherwise, the extraordinary course by which the policy of the fundamental laws themselves may be reviewed, as occasion shall require. Both these precautions have been introduced and satisfactorily applied by the founders of the United States. But they are not wanted for this purpose by the English constitution. For, notwithstanding a few fanciful conjectures, as above, at times incautiously or intemperately hazarded, the English constitution is not established on any strictly fundamental laws, and still less are any specific questions reserved by it for the direct intervention of the people. But there are analogous dilemmas which may arise under it as a limited and a mixed monarchy. Many, indeed most, of these dilemmas appear to be left open to the chances of unnecessary aggravation, by the want of some similar arrangement. A government, composed of several members with distinct powers, can only exist as such on the supposition that they each remain content with their own share, or that, in case one should trespass on the other, the irregularity can be set right by recurring to expedients legally providing for the emergency. Every one of the triple divisions of the English legislature has in its turn made experimental encroachments, against which there exist but imperfect and often very circuitous guards in the constitution. By the law of constructive contempts, once so flagrantly abused, either house of parliament is armed

Government and Laws.

with a despotic weapon. This weapon is beginning to gather a prudential rust in the sheath at present; but the want or the jealousy of a superior court is a poor excuse for allowing it to continue there at all. The mysticism belonging to the maxim that the king can do no wrong, coupled with the recognised absence of any remedy against the crown for any possible amount of misgovernment, proved the ruin of the Stuarts. It encouraged them in the opinion that the supreme power was lodged, not merely in part, but wholly, in the sovereign, and that it might be abused with legal impunity. The 16th Charles II., as renewed by 6 William and Mary, declares that a new parliament shall be called within three years of the determination of the former; but no measures are taken by either statute for the assembling of a parliament in case the king should not choose to call one. The security is left to the old indirect check, the stoppage of the supplies, and to the new one, which, by means of the annual mutiny act, has been derived from a source where an aid to freedom could hardly have been expected, namely, the innovation of a standing army. There is at present abundance of rectifying principle and of auxiliary appliances in the sounder portions of the English constitution, which will prop up the rest, and hold the feebler part to its work. Otherwise the history of the Habeas Corpus act is a striking proof of the inadequacy of all general declarations. In doubtful times these are merely waste paper, unless accompanied by positive arrangements for carrying them into execution, and subjected to proportionate penalties on their infringement and neglect. The act of 16 Charles I. had provided, that if the king neglected to call a parliament for three years, the peers might assemble and issue writs for choosing one; and, in case of neglect by the peers, the constituents might meet and elect one themselves. This act was repealed with great ignominy at the Restoration. But it seems to have left the crown its due precedence, and to have provided, with as little impatience as possible, for the securing an object which all parties are agreed it is absolutely necessary some way or other to secure. The debates upon the command of the militia previously to the breaking out of the civil war, are a memorable instance of the folly of leaving great constitutional rights in obscurity up to the fatal hour when they can no longer be settled calmly and on reasonable terms. If it be important to define rights in times of tranquillity, it is no less so to provide the particular forms by which, in case of violation, the remedy may be applied. It is true that these collisions approach to the character of revolutions. When a king has so far separated himself from his parliament, there is little chance of their returning to that harmony by which alone a constitutional monarchy subsists. No previous arrangements can completely meet the crisis after it has occurred; but they may mitigate its severity, and, by the mere fact of their known existence, may do the still more acceptable service of preventing its occurrence.

According to the third and remaining plan, the constitution recognises the existing legislature as supreme for all purposes whatsoever. To this plan the English nation has always stedfastly adhered. From the time when the commons of England were adopted into the legislature (49 Hen. III.), or shortly afterwards, the legislature has, without any deviation worth mentioning, been the parliament; that is, the king, lords, and commons, in parliament assembled. The popularity of parliaments has been so paramount throughout, that the public have never until recent times been tempted to look elsewhere for rules, inclinations, or opinions. The supremacy of parliament kept its hold, like an anchor which nothing could shake, in the most stormy seasons, and under every variety of circumstance. The impossibility of complying with the customary forms was satisfied as often as it occurred, by the nearest approximation which could be obtained. This was no less remarkable in the course taken as far back as the supposed resignations of Edward II. and Richard II., than on the later occasions of the imperfect convention parliaments. Nobody suggested the propriety of calling together the people to restore Charles II., or to instal William III. into the vacant throne. Mr Hallam observes, that in the combination of gift, descent, and popular election, which took place on the accession of Henry IV. in the year 1399, there was as great formality as in 1688, making due allowance for times and men. The semblance of election remained with the members of the *quasi*-parliament. They had been summoned by the king's writ, but, from not having his commission, they did not take that solemn name, and only called themselves the estates of the realm. Wherever it was possible to preserve by fictions the appearance of a regular parliament, fictions were called in. Thus, during the infancy of Henry VI. the shadow of the royal infant, then only nine months old, opened his first parliament, and made appointments during pleasure. On the derangement of George III. the regency was appointed under the great seal. To keep up the entireness of the body politic of the state, the cooperation and personal will of the king were necessarily assumed in the very act which was to supply his personal incapacity. It was from the court of parliament that Richard III. obtained a confirmation of his alleged title. He rested upon it as "the known quieter of men's minds;" and the Earl of Surrey appealed to it as the one conclusive authority, when taunted afterwards by the successful competitor for the crown upon Bosworth Field. Though Wolsey, "hating parliaments," which therefore hated him, "had been the means that none was holden in the realm but one for the space of fourteen years;" yet Henry VIII. told them that he was informed by his judges that he was never so great as when sitting there in his estate royal. The great test of the omnipotence of parliament was its power of altering the succession. This, which was the established doctrine of the prior period, it was by a statute of Elizabeth made treason to deny. At the beginning of the civil wars, Charles I. called the peers together at York; and the cavalier members seceded from the House of Commons. Under these circumstances a metaphysical question might easily have been raised, as to which was the real parliament. But the locality of Westminster was like keeping the field of battle. It decided the direction of that wonderful and superstitious homage, which made Clarendon complain that "an implicit reverence for the name of parliament was the fatal disease of the whole kingdom." The substance and vitality, however, of the institutions to which the entire authority of national legislation is transferred, are still more important than the name. For this purpose their independence as intelligent deliberative assemblies must be secured. No question can be made concerning open violence. Any attempt by intimidation to force the repeal of a law or a change of measures, or to overawe either house, is treason. But, further than this, no minority or fraction of the people must be allowed to exercise over the legislature an influence of opinion, which the constitution does not attribute to the people at large, or at least does not provide them with the means of exercising. This is a subject of great delicacy; but still there must be some limits. Accordingly, both in law and practice, limits more or less elastic have been put on the nature and degree even of the moral pressure which may be urged on parliament from without.

Tumultuous petitions having been carried to a great excess during the long parliament, the statute 13 Charles II. in consequence, imposed several restrictions upon petitions for any alteration in church or state. But notwithstanding the opinion of Mr Dunning, and the present practice, these restraints have been judicially determined not to be affected by the bill of rights. Mr Hallam says that he has traced public meetings for the debate of political questions no higher than the year 1769, and, subject to very few exceptions, petitions simply political not quite so high. Rights of this kind, guaranteed to the body of the people, and liberally construed, appear to be supplemental to a representation which stops short of annual parliaments and universal suffrage. They are the democratical counterpart to addresses of loyalty to the throne, and of confidence in the government, which are said by Evelyn to have come in even in the time of Cromwell. The right will probably not be used, certainly not used frequently, till a want of sympathy between the representative body and the people, or particular classes, begins to be suspected. The sense of the public, so taken, may often be found to clash with the sense of particular constituencies. In this case, two questions necessarily arise for a member's consideration: first, what weight either one or the other ought to have as mere authority in overruling his own opinion; and, next, which of them, in the event of competition, is entitled to a preference. The same constitutional answer will apply to both difficulties. The inclination on the part of the English constitution appears to have settled down, after some previous oscillation, to one consistent course, as soon as the commons began to feel and act up to their real dignity and strength. A member must necessarily be returned for a particular place. The question is, Are his duties therefore local? The terms of the writ of summons had all along plainly signified that, although chosen by a single district, he was chosen for the wants and service of the realm. Nevertheless many instances formerly occurred of the commons begging for time to consult with their constituents. It may naturally be presumed that this was nothing more than a timid way of evading unreasonable requests. Because their ancestors, afraid of Edward III.'s designs upon their subsidies and fifteenths, had declined to be made consulting parties to his wars, it was absurd in James I. to imagine that he could altogether call away from politics the English gentry of his day. Yet at so late a period no less a person than Burghley condescended to argue against the propriety of the interference of the House of Commons in matters of war and peace; and to take the distinct ground that its members by its institution had minds only of a compass each for the place which he served. But parliament had already heard the contrary within its walls. The movement of society which had made it impossible to execute the statute requiring the member of a district to be an inhabitant, had brought out, in the reign of Elizabeth, the first parliamentary declaration in behalf of the complete legislative authority of members of the House of Commons, in full accordance with the letter and conditions of the ancient writ. In the declaration that members were to act not only for their constituents, but for the whole kingdom, it was evident that a great principle was proclaimed. If sycophants then contested it, Mr Hallam, speaking of modern days, says very truly, that it is one which at present "none but the servile worshippers of the populace are ever found to gainsay." The weightiest arguments in Burke's letter to the sheriff of Bristol, against particular instructions, are little more than the application and extension of this principle. The necessity of going back to their constituents for a specific assent, was one of the main grounds of that incompetency to the duties of a representative assembly which facilitated the ruin of the states-general of France. A few votes beyond what a question would have obtained upon its general merits may thus be stolen, and a few individuals may thus push themselves forward into temporary notice. But public opinion can never be truly ascertained, any more than the public interest comprehensively promoted, by desultory and individual pledges. For this purpose the public must act in concert. With this view, kings of England have sought to satisfy themselves and the House of Lords with regard to the reality of the public sentiments, by a dissolution addressed to specific points. On the occasion of Mr Fox's India bill, the new members were expected to bring to the House of Commons an answer concerning the royal choice of particular men as ministers; and on the occasion of the Reform Bill, concerning the policy of a particular measure. This is the utmost advance which the English constitution has made towards admitting the doctrine of the will of the people or the instructions of constituents. So narrowed, it is a proper, and at times an indispensable part of every rational system of representation. It is practically quite consistent with the general rule that the select body of electors are trustees for the entire community; and that their representatives are the only organ by which the public will is on all subjects ultimately and conclusively expressed.

This then is the English system. It seems to be an extreme and fanciful subtilty to doubt whether the title and character of a constitution can properly belong to it. It is something in its favour that it can appeal to experience as practically embodied in a government, now of ancient standing, at once the most progressive and the most permanent which the world has ever yet seen. Why is it less a constitution because it gives to its ordinary contemporary legislature the most plenary attributes of supreme political power, and because it disclaims the supposition that its early constitutional legislation had or could have the sanction of any higher authority? The assent of any one generation can be of neither greater nor less value than that of another. It is not wonderful that a society, setting up for itself for the first time, or obliged by circumstances to begin anew in an enlightened age, should try to build upon the basis of fundamental laws. But it is fortunate for a constitution, of which the first stone was laid in haste and ignorance, and in the dark, and which nevertheless always kept so far in advance of its contemporaries, as to serve other nations for the model whence the criticisms have been derived by which its irregularities were afterwards to be condemned, that it started with no similar pretensions. If it were to suit the ages through which it was to endure, it could only do so by a plastic mode of conformation. In this manner its people were educated along with it and up to it, the two acting and re-acting upon each other. Hence an instinctive intelligence and conformity, otherwise almost unattainable, appear to have been secured, which political changes have hitherto slightly disturbed. Some bad logic, and a few incidental anomalies, are a small price to pay for conciliating opinions and smoothing over the transitions through which, in the course of centuries, an improving nation has to pass. But the mode in which these alterations have been made is objected to. The body of the people, it is said, ought to have legislated upon them in their own persons. It is surely a sufficient answer that it would be difficult to name a year, when in point of fact more would not have been lost than gained by tying up the hands of parliament, and putting its legislature to the circuity of an appeal to the freeholders of the county courts. The nature of things does not admit of there being any greater security for good government than can be given by a legislature of which a popular representative assembly, properly chosen and seasonably renewed, is a member. To call in the people to council, is to abandon to that extent, under circumstances too of great probable excitement, the advantages of representation; and for no countervailing benefit, unless on the singular supposition that a people incapable of choosing able and honest representatives, will be found capable of being able and honest legislators themselves. The device is much more likely practically to delay improvement than to check encroachments; since, for the latter purpose, the restraints it imposes are either unnecessary or insufficient. There can be no substitute for the spirit of a people. With that spirit, these precautions are not wanted; without it they are vain. The two cases which look most suspicious in English history (one in substance, the other in form) are the proclamation-statute of Henry VIII. and the septennial bill. The parliament of Henry VIII. gave royal proclamations in certain cases the force of law. The extent of the innovation has often been exaggerated. But, with regard to the present question, there can be no doubt, that a generation which by royal order changed its religion four times in twelve years, would, on the subject of royal proclamations, have as readily acceded to his majesty's desires. A few corporations petitioned against the septennial bill. But an observer of the prior, contemporary, and subsequent conduct of the body of the people on this point, and a reader of Burke's speech against triennial parliaments, will perhaps see little reason to believe or to wish that the people, if calmly consulted, would have come to a different conclusion. It should be recollected, that the question is one of pure argument only, and not of history. By the common law a parliament, unless dissolved, lasted for the king's life. In 1694 this duration was first shortened to three years; but in 1717 these three years were lengthened to seven. Thus, the law of triennial parliaments, spoken of by some as an almost vital part of the English constitution, was never known in England but for neither more nor less than the space of twenty and three years.

Every government is characterized by the ends which it proposes as its primary objects, and by the means which it applies for the attainment of its ends. These objects represent what is vaguely called its spirit. The only means properly at its command refer to the making, interpreting, and executing laws. It follows that the most important distinctions in this respect between one government and another, must be found in the specific provisions which determine the formation and distribution of the legislative, judicial, and administrative power. The English constitution is a limited or mixed monarchy; limited, by the maxim that the king has no rights but those which are prescribed and ascertained by law; mixed, by the fact that the parliament, in which the sole legislative authority resides, consists of the king and the three estates, the nobility, clergy, and commonalty of the realm, as comprised in the two houses of Lords and Commons. The suppression of partial interests is sought to be attained, and the practical recognition of the great end of government, namely, the happiness of the whole body of the people, has been principally developed and enforced by the share which the people exercise more or less in the government. This takes place in the legislative department, by means of their representatives; in the judicial, by the agency of the jury; in the administrative, by the doctrine of official responsibility, and from the example and control of a great diversity of popular local municipal institutions.

A more considerate legislation is promoted by a second legislative assembly. A great addition is also made to the political stability of a limited monarchy, by forming the members of this second assembly into an hereditary nobility. A mixed government has, however, a still greater advantage. It naturally leads to and facilitates a division of powers, which is the most important of all the checks that mere arrangement can produce. According to this division, the authority of parliament is strictly confined to the original enactment of the laws. The duty of the judges is as strictly judicial. They have no more to do with the politic administering of the law than with the making of it. The law being thus made, and thus interpreted, the entire charge of carrying it into effect is vested immediately or mediately in the crown. Whilst the several parties who make, interpret, and execute the laws, are kept, in this manner, perfectly distinct, it becomes exceedingly improbable that any confusion, either unintentional or wilful, should arise between the principles properly belonging to their several operations. This is a caution which the cause of public liberty, as well as that of civil justice, alike imperatively require. Blackstone[1] has expressed a strong opinion as to the propriety of the executive being only a branch, and not the whole, of the legislative; also[2] that the judicial authority should in some degree be separated from both. This was one of the points on the paramount importance of which Jefferson and Adams were agreed when they came to apply the experience of the English constitution to the construction of their own.

Eastern nations, notwithstanding their supposed immemorial civilization, appear never to have got much nearer than the inhabitants of the South Sea Islands to a conception of the just foundation on which alone the rights and duties of sovereignty rest. On the other hand, the citizens of Greece and Rome were fully aware that political society was grounded on the advantage of its members. Their patriotism was not more exalted by the pride of national independence than by the consciousness of being responsible only to the law. Nevertheless, the real condition of these great commonwealths was for the most part in lamentable contradiction to the individual ability and virtue by which their history has been made famous throughout all ages. The glory of free and classical antiquity was frequently clouded, and was brought at last to an abrupt and final termination. This is apparently to be attributed to the defective mechanism of their institutions, more than to any other cause. Their construction and division of the legislative, judicial, and executive authority were all along so imperfect, that their negligence of the means of a better political arrangement can only be accounted for by their ignorance of its necessity. There is nothing to this effect, even in their theoretical works upon government, when carefully examined. Polybius, it is true, gives the preference to a combination of monarchy, aristocracy, and democracy, as being in a degree more stable than the simple forms. Cicero also agrees with him in saying, that this was the true Roman constitution; but he most unwisely adds, in compliance with the Roman jealousy of kings, that wherever the executive is placed in a single hand, the government is mixed only, not tempered, and must be ruined by the vices of the individual. Different writers appear to have meant different things by the same word. Aristides denominated the government a mixed one as late as the time of Marcus Aurelius. Tacitus saw through the fictions, and thought that the word implied more, otherwise he would scarcely have said that such a combination may be more easily praised than effected, and that were it effected it

Government and Laws.

could never be lasting. In case, however, the constitution had done nothing further than realize the above combination in the general sense which alone these philosophical statesmen were contemplating, it would have stopped infinitely short of the principal benefits which it has conferred. The separation of the three great branches of political authority into distinct departments, as it is one of the most probable consequences of a mixed monarchy, so is it beyond all comparison the most valuable. Unfortunately it had not taken place under the imperfect specimens of mixed government with which they were acquainted. It is not surprising, therefore, that in theory the philosophical truth of such a corollary should never have occurred to them. If that consequence had been duly presented to his mind, Tacitus must surely have seen reason to question the cycle of Polybius, and to feel greater confidence in the political contrivance by which the efficiency and the durability of states have both been found in practice to gather equal strength. No political phenomenon can be more interesting than the circumstances and the method by which a government has thus arrived at the high distinction of first uniting improvement and stability, liberty and order, and has been enabled to combine the greatest of all ends with what, from the failure of the most celebrated experiments, it may be well supposed were means very difficult both to discover and to apply. Sanguine spirits often appear to imagine that as good a constitution as can be devised may be struck out and fitted upon at a moment's notice. The history of the English constitution may teach them greater caution. A distinct examination of its respective parts will show, not only how slowly they have been formed, but to what extreme risks at different periods the existence and the principle of each have been, and perhaps must be, severally exposed.

The English constitution is more historical than philosophical. It has been the gradual development of national good sense, shown in a spirited and prudent improvement of tendencies and events, without any of the ambition of a regular, preconcerted system. Its object was never stated in a declaration of the abstract rights of man, nor its organization derived from a metaphysical analysis of the elements of human nature. He must have been indeed a prophet, who, at the time of the Norman conquest, could have foreseen the course by which it would outstrip the feudal monarchies which resembled and surrounded it. The difference lay in this: For successive centuries, circumstances played favourably for a people who had the merit or the good fortune to profit by them as they occurred. M. Rey is so far right. England has experienced the truth of Aristotle's observation with regard to Crete. An insular position has great advantages for political experiments. Assistance has also frequently come in from the most unlikely quarters, and the scale has more than once been turned by causes to which, as far as we can observe, no nobler name than that of accident is to be assigned. At one time the very strength and concentration of the monarchy of England, as compared with the weakness of the monarchy of France, brought the barons, the people, and even the church, into a closer union for their defence. At a later period the impoverishment of the crown by foreign wars, and the alienation of the crown lands, brought it into dependence upon, what was most fortunately, one national parliament instead of several distinct provincial assemblies. The separation of the greater from the lesser barons, the assembling of the commons and the lords in different chambers, the transit through which the exemptions claimed by the clergy became disqualifications, the conversion of the jury from their original character (whatever that may have been) into a popular tribunal, have turned out to be the hinges on which English freedom has ultimately turned. They are instances of incidents, in themselves at first comparatively trifling, diverted by circumstances into a deeper channel, or transmuted by a noble alchemy into a much higher purpose than what was their original purview and intent. Although the English government was from the first a limited monarchy, it was not for nothing that monks and lawyers lent a hand in the pious frauds of forging tales about Alfred, Kentish privileges, and imaginary Saxon laws, or in encouraging the more recent fiction of the notorious anti-tallage statute. The stoutest antiquarian who ever argued that the title of William the Conqueror represented merely the feudal *conquisitio*, and not the conquest of the nation, nevertheless must admit from time to time great historical distinctions. The nature and degree of the limitations practically needed and applied to the powers and mechanism of the several component parts of the government varied exceedingly at different periods. The importance even of the grand division between the legislative, judicial, and executive authorities, was far from being at once recognised and observed.

Changes in society and opinion.

A constitution upon paper and in practice are such very different things, that we must look into the history as well as the laws of a country, in order to know at any given time what was the real contemporary character of its government. English antiquarians have been more or less successful in tracing back the dates of their most popular institutions. But the sense in which the same institutions were in point of fact understood and administered at different periods, and the security which they were capable of affording, are distinct and much more interesting questions. A people and their government, it is true, are always cause and effect to each other; and none more so than those of England. In the present instance, however, there can be no doubt but that the narrative of English parliaments and of English juries establishes their existence, as a matter of pedigree, long before there was spread throughout the community either the spirit, the knowledge, or the means to turn them to their legitimate account. The systematic regularity of modern governments was unknown even to the ancient republics. No wonder, therefore, that it was wholly unthought of either by the feudal chieftains themselves, or by the rude vassals who attended to do suit and service at their courts. Our ancestors were satisfied, we are told, with the rough standard of measurement taken from parts of the human body, though differing in different men, till Henry I. ordered the *ulna* or ell, which answers to our modern yard, to be made the precise length of his own arm. To lay down any thing like a precise standard for civil obedience, was left for later times, and for arms still stronger than those of any king. Even long after the golden rules and metewand of the law were recognised at Westminster, acts of violence were frequent over the kingdom, with more or less remonstrance; so that *judicandum est legibus non exemplis* is a maxim which the constitutional inquirer is obliged to keep constantly before him.

The history of England opens with a society divided into castes. The distinctions taken by the law were onerous and severe. There is a great difference between Glanville and Beaumanoir. Nevertheless, the blot upon Magna Charta itself, in the limitation (*liber homo*) cannot be explained away. The later threat of Richard II. after the unsuccessful insurrection to which the peasantry had been driven by oppression, is equally intelligible. Their condition, he told them, should be made yet more miserable. The statute of labourers, which was passed in the reign of Edward III., was in the same spirit. It continued to be a no less absurd than wicked favourite with after-

Government and Laws.

times. It is impossible to look over the whole intermediate legislation concerning the lower orders down to the reign of Elizabeth, without perceiving that most of its provisions are as much statutes of police as of trade. They have the air of being expressly directed to the object of preventing the consolidation of the different degrees of society into one people. When we compare the laws of England in this respect with those of the continent, we cannot estimate too highly the comparative equality of ranks, and the absence of exclusive privileges. Nevertheless the laws were bad, and public opinion worse. The dialogue on the Exchequer, written towards the close of the reign of Henry II., observes, that in all cases of secret slaying, whether of English or Norman, the penalty should be levied on the hundred, "unless there are plain *indicia* of the servile condition of the deceased." The petition of the commons to Richard II. that villeins might not be put to school and so get on in the church, "for the honour of all freemen," was re-echoed two hundred years later, in the cry against the Lord Cromwell, on account of his "villein blood." The class was then about to disappear. It is evident that it was only by its extinction that prejudices incompatible with real equality under a free constitution could be removed. The gradual elevation of the entire population into the condition of freemen, put all ultimately in possession of rights which had been wrested from the crown by feudal leaders and independent yeomen with a much more partial object. It took ages to compass this emancipation, and to reverse the proportional shares of the national wealth, as held by the king, the church, the nobility, and the commons. If all the land of the kingdom had continued to be the portion of the church, the king, and the immediate tenants of the crown, who, according to the list in Domesday-book and Brady, did not exceed seven hundred in number, this consummation would never have been accomplished. Civil wars and commerce, by scattering properties and displacing chivalry, broke up the feudal system much more effectually than any positive enactment. The possession of property gave leisure; leisure, especially when the reformation and the press stirred up the human mind with new and more liberal excitements, gave knowledge. Even without the strength of numbers, the combined influence of property and knowledge must give power. Until the body of a people has obtained the intelligence necessary to understand something of their own interests, and the power of making an attention to their interest and feelings a matter of prudence on the part of the higher classes, it is in vain to expect that just principles of government will be steadily acknowledged, much less that they will be steadily put in practice.

The king appears in the law-books as the source of almost every institution and every right. There is no other independent political existence save his baronial court. Nevertheless, as far at least as concerned the people, the king was originally still more powerful in fact than even in law. There was always a legal control upon him. But it was lodged at the beginning in an assembly where as yet the people bore no part. Bracton, who wrote under Henry III., probably not long before Leicester's writs to knights, citizens, and burgesses, appears to have as little anticipated them as he could have anticipated their effect. In his perversion of the imperial law to the purposes of a limited monarchy, he declares that the will of the prince must be according to his counsellors; that is, of "his court of earls and barons." He terms them his "associates," and makes them his superiors; for he adds, "were the king without a bridle from the law, they ought to put one on him." The court of peers, or royal council of France, by the non-attendance of the tenants in chief, sunk into the great judicial tribunal of the country, and became known by the name of parliament, after the time of St Louis. The peers of England were not so confident of their feudal exemption from supreme legislative control; consequently, when, about the same time, or a little earlier, the *aula regis* or great council of England assumed a new form, it separated into two compartments; one judicial, or the supreme courts of justice; the other legislative. The last consisted originally of the earls and barons only. By the time that the incipient House of Commons became its colleague, the name of parliament was appropriated, and, from its omnipotence over the feelings of the English nation, has become almost consecrated in their behalf. It was long before the parliament felt its strength, or knew how to use it. In the mean while the constitution, directly or indirectly, within doors and without, kept making head. During the struggles which the crown, reign after reign, was maintaining, sometimes with different members of the royal family, at others with the aristocracy, and at others against the church and papal usurpations, the people became important as allies. The people appear on the whole to have judiciously sided, where, according as the temporary pressure was felt to bear, it was for the interest of the public that they should side. It is difficult, owing partly to the uniformity which prevails at present, to comprehend the sudden turns which this instinctive policy might call upon them to make.

A sagacious and honest yeoman may have been with King John to-day, and with his barons to-morrow. To look merely at property: the Conqueror retained in his own hands fourteen hundred manors, the reserved rents on which Burke, in his Abridgment of English History, reduces to L.70,000 of the money of that period. The resumption of the grants of Henry VI. was prefaced by a public declaration that his ordinary income did not amount to more than L.5000. In the next reign we find Edward IV., independently of parliamentary supplies, the owner of above a fifth of the lay property of the kingdom. Within half a century the scale had again changed its balance. Wholesale confiscations, succeeded by the minuter and more politic arts of Henry VII. humbled the pride and broke the combinations of the nobility. Although the nominal rental of the royal demesnes was reduced to L.32,000 at the accession of James I., yet the idea of any danger to the monarchy from aristocratical competition was almost a faint tradition at the time of Lord Russell's trial. He justly exclaimed, in allusion to the apprehension, "We have no great men now." Previously to this revolution in society, it depended for the most part on the personal capacity and character of the sovereign, whether the contingencies to which a wise constitutional jealousy ought to have been most alive, would come from the turbulent intrigues of the aristocracy, or from monarchical ambition. The royal prerogative attracts the first and the liveliest attention, as its power is always present and most promptly felt. Besides, it was absolute in language, prominent in form, and often irritating in the subject and occasion of its exercise. But all the great points whence a cloud might have arisen over the freedom of the nation had been soon foreclosed, and, in spite of occasional, indeed numerous violations, were closely watched. There is no denying that many remaining prerogatives were absurd and even odious. Still the nature and the danger of the grievances to which the people were legally and practically exposed from them are usually overrated. The Stuarts let no prerogative drop willingly; and it is well known that they laboured hard to revive some that were obsolete. Yet Lord Bacon declared, on presenting an address to King James, that there was no grievance in the kingdom "so general, so continual, so sensible, and so bitter, as the prerogative of purveyance." Nevertheless, what did it amount to when represented in money? From one cause or another, the commons receded from their negotiation, rather than buy off this their master grievance, and that of military tenures into the bargain, at the cost of an annuity of L.200,000. In the interval which elapsed between the depression of the nobles and the rise of the commons, the monarch had the stage comparatively to himself. The crown also at that critical moment passed into a line of able and haughty princes. Mr Hallam observes, that constitutional freedom was consequently retrograde from Henry VI. to VIII.; yet it is evident, from what passed during that period, that the hardy plant was not only alive, but safe. Bills in the form of acts, instead of petitions, which by adding to or diminishing from what the commons had petitioned for, had been for ages scandalously abused, begin with the reign of Henry VI. The first writ of habeas corpus, apparently so simple a result of Magna Charta, was obtained against Henry VII., the wiliest of the Tudors. Elizabeth had her father's spirit, and can scarcely be suspected of relaxing a hold which she could have decently retained. Yet in 1586 the House of Commons first succeeded in bringing the inquiry into election returns from out of chancery before themselves. By unfairly selecting the arbitrary passages from the reign of Elizabeth, and misrepresenting them as the ordinary course of her government, Hume gave both colour and currency to sophisms, which betrayed a much greater passion for ingenious paradox than for historical truth. The English people are wrong, it seems, in charging the Stuarts personally with the misgovernment which provoked the great rebellion. That misgovernment is represented to be nothing more than a continuance of the ancient English constitution, such alone as their ancestors had known it. According to this statement, the fault of the Stuarts would have consisted in carrying down the prior constitutional misrule into times which would no longer bear it. If such had been the fact, it is a fact which those times must certainly have known. But the understanding of contemporary parties was plainly all the other way. History has preserved the positive admission of Charles I. to the contrary, in a reference too remarkable not to prove that he was himself conscious of, and was aware also that his subjects knew, the whole extent as well as spirit of his innovations. What a satire on his own and on his father's government, that he should, in 1640,[1] hold it out to his parliament as a boon, that he would return to the precedents of a sovereign whom they had already endeared to the people as "Good Queen Bess;" whose reign, however, we know, notwithstanding, to have abounded with tyrannical executions, gross and frequent enough, it might have been thought, to have satisfied any of her successors. It is not the less true, that the time had come when the authority as well as the ceremonies of the court must undergo mutations, at which minds, with much larger views of government than that of Clarendon, would be startled, and perhaps annoyed. The state of society required popular changes to be admitted, for which no precise precedent could be found. Under these circumstances, men like Selden, for instance, a little too apt not to look for liberty beyond their law-books, must often have felt embarrassed how to act. The Stuarts, however, did as much as could well be done towards relieving their subjects from difficulties of this description.

Unluckily for the Stuarts, none of the innovations which they attempted, nay not even the consistent system to which it had been their object to bring the practice of their government, were so new and so outrageous as the principles on which they professed to reign. No country set a higher value than England, whether it was pleaded on behalf of the prerogative royal, or in the much more reasonable case of civil possessions, on the somewhat too stationary title of prescription. The coronation oath on the one hand, and the oath of allegiance on the other, the theory of the feudal system, and many passages in their annals, had accustomed them to look to a rough notion of contract as the criterion of submission. The divinity studies of the early lawyers, and the usages of the puritans, tended to influence the thought and language of modern times by the course of authorities in the Old Testament. But these views were common property. All went there for what they wanted, and all found it. The partizans of despotism and freedom, Hobbes and Locke, Bossuet and Algernon Sidney, discovered, the two first in Chronicles, the two last in Deuteronomy, arguments for their opposite systems. It was far otherwise with the novelty which the Stuarts took up, and made the creed of their supporters. The new creed was precise and positive, and the whole spirit of English history was in contradiction to it. No later than the 13th Elizabeth, a statute had been passed, declaring it treason to maintain in any wise that the king and parliament had not the power to limit the succession. It was natural to lament that the feeling of feudal attachment was decayed. But the doctrine of a divine hereditary patriarchal right was a strange invention to replace it withal. The cavalier loyalty of Ormond belonged to former days, and had nothing in common with the superstition of Mainwaring and Sancroft. Principles utterly inconsistent with all that had been ever written on the subject, almost with all which had been ever done, became the favourite and insulting theme of speeches, proclamations, sermons. Thence the dread of the convocation sitting after the dissolution of parliament; thence the unanimous resolution that their new canons would not bind even the clergy; thence the protests against the new pulpit law, to make the king more absolute than his predecessors. Roman Catholic ecclesiastics had put their hands to Magna Charta. The Oxford decree was the boast of the Church of England. The latter books of Hooker, on account of their heretical latitude, were to be made out to be fabrications; whilst Jeremy Taylor, the great ornament of his profession, pronounces that there are few cases of conscience in which a man may hope for half as much conviction as on passive obedience and non-resistance. Non-resistance was soon improved into absolute compliance. It became, in other words, the indefeasible legitimacy of modern days. These prodigies of doctrine defeated themselves. They misled the governors and provoked the governed, and, in James the Second's expostulation with the seven bishops, returned them their poisoned chalice to their own lips. A limited monarchy and unconditional allegiance are a contradiction in terms. The only consequence of allowing to a brave and thinking people rights and privileges in the statute-book, and yet closing up every practicable channel through which, if they are violated, a legal remedy can be obtained, is the generating a spirit which sooner or later must force itself a way by some great convulsion. Another revolution, and the example of a new dynasty, were made necessary to establish the truth of the opinion which Gourville expressed in vain to Charles II.: "A king of England who will be the man of his people, is the greatest king in the world; but if he would be any thing more, he is nothing at all." So evident, indeed, has it ever been since the Revolution, that no king can long carry on the government upon any other terms than by becoming the man of his people, as represented in parliament, that the royal legislative negative has fallen into abeyance for a century and a half. Elizabeth, at the close of one session, rejected forty-eight bills which had passed both houses. The last exercise of this prerogative was in 1692, when William III. refused his assent to the bill for triennial parliaments. With the modifications, and under the circumstances in which alone the negative of the president of the United States can be interposed, it is easy to see how the head of that republic may prudently venture on the exercise of a power to which it would be the height of imprudence in a king of England so far to put himself in opposition to both houses as to revert. It cannot be said that the change is in the mode of operation only, and that the king does now by influence what he used to do by prerogative. It is notorious that, on several occasions since 1692, influence has failed in doing that which the acknowledged prerogative would have done by its single word. The result is, that the king, who for many centuries was more powerful in fact than in law, is more powerful in law than in fact at the present time.

---

[1] "At the opening of parliament, the king very frankly delivered himself to the lords and commons, and was resolved to follow their advice in repairing the grievances at home, which he confessed the necessities of the times had brought upon his people. All those, whether in church or state, he was willing should be removed, and desired that all things might be reduced to the good order and practice of Queen Elizabeth; which to the people of England were sure looked upon with the greatest reverence." (1. Clarendon, 519.) This important passage is printed for the first time in the last edition. It is one of the worst omissions in the former garbled text. The speech is imperfectly given in the parliamentary history, with a rather later date. It is in itself a complete answer to the comparison laboured by Hume. The truth is, that the Stuarts had a dread of English history, for its testimony against them. Bishop Nicholson observes, in his *Historical Library*, that the publication of the second part of the Glossary of even the orthodox Spelman was supposed to be delayed, because he had called Magna Charta, *Libertatum Anglicarum diploma et sacra anchora*; and that in 1614 the Society of Antiquaries was suppressed on account of the jealousy manifested by James I.

If under the same forms the rise of the commons has changed imperceptibly, but entirely, their relative position with regard to the crown, this has happened to a still greater extent between them and the barons. The power of the nobility consisted in their immense possessions, in the clan-devotion of their dependents, in their territorial jurisdictions, and in the original superintending authority of the supreme feudal court. The blow struck at their properties, both by force and artifice, speedily took effect. The shake once given was so certain of spreading further, that the formation of new aristocratical fortunes out of the monastic confiscations has never been made an imputation on the policy of Henry VIII. It was as the favourite of Elizabeth more than as the lord of Kenilworth, that Leicester succeeded in making the gentry of Warwickshire wear his livery. The original relation between lord and tenant implied protection on the one hand, and obedience on the other. If the tenant could not alien without the lord's license, the lord could not transfer the tenant's seignorial dependence without the consent of the tenant. The social movement, commencing at the top, naturally occasioned a relaxation in these duties and sympathies on the part of the lord in the first instance. This broke the charm. It soon became evident that king-maker could be the title of no future Warwick. There had been a series of concentric circles, through which the feudal feeling rose from the vassal of the mesne lord up even to the throne. But all gave way at once. It was clear that the mischievous distinction between a king *de facto* and a king *de jure* could not be recalled, nor the allegiance of the subject transferred from the regal office of the sovereign to his natural person and blood royal, when once the feudal feeling lower down the ladder had been so completely destroyed, that, in the words of the age of Selden, an English tenant would be the first person to lay his landlord by the heels. The landlords and the sovereign have been both amply indemnified in increased security, for whatever either may have lost. At the same time the constitution and the country have been infinite gainers by the general adoption of a more rational patriotism. The civil exemptions which the peers possessed in their individual character were all along insignificant. The judicial authority vested in their territorial jurisdictions was superseded by circuit judges, and by justices of the peace in every county. That which had been reserved to them collectively was of a kind more honorary than formidable, and one which there was little temptation to abuse. The small value which they attached to their power as a civil tribunal is proved by the intermission which took place of all writs of error to the lords from the time of Henry IV. till the accession of James I. Their criminal jurisdiction, except in the case of impeachment, was confined to the members of their own order. From the time that the commons were united with the lords, and their joint assent became equally indispensable to all legislative measures, the sole undivided glory of Bracton's baronial court was at an end. A statute of Edward II. declares that every legislative measure not sanctioned by the consent of king, lords, and commons, shall be void. It states also that this is according to custom. Nevertheless it was long before the commons had the courage to act upon this supposed equality. Sometimes they stultified themselves by way of policy, to avoid any possible responsibility. On ordinary occasions they felt themselves overshadowed by the neighbouring greatness of the lords. Thus they applied to them on great emergencies, begging that they would send some of their members to instruct them in their duty (as in 1st Richard II.), "on account of the arduousness of their charge, and the feebleness of their own power and understanding." In the same manner, on the insanity of Henry VI. they left the establishment of the regency with the peerage. "You, the peerage, in whom, by occasion of the infirmity, resteth the exercise of his authority." In the reign of Charles I. the commons are seen for the first time taking the lead, and carrying the lords along with them. Several of the lords in that crisis gave in their adhesion, and co-operated with the commons. Before this, the spectacle of their concurrence had always been, the commons walking in the train of the lords. New principles must accompany such a change. The House of Peers could no longer claim the privilege of legislating exclusively for the benefit of their order, nor proceed on the distinction that they sit in their own right, answerable only to themselves; whereas the House of Commons, as a representative body, is answerable to the people. The sophistical distinction can hardly serve at present to prop up the privilege of their proxy; a pretension not less incompatible than popular instructions with the first duty of a deliberative assembly. Fifty years ago, when Paley first published his Moral Philosophy, the peers had so far fallen into the back ground, and political reasoners had so far learned to look to reason only, that Paley defends the institution of a House of Lords as a part of the British constitution, on grounds which would have amazed Simon de Montfort, and perhaps somewhat scandalized John earl of Somers. His main argument is founded on the use of a second and totally distinct legislative assembly, in order to protect the state against popular caprice and fury. Ever since the Revolution, the *momentum* in English legislation has lain necessarily in the commons. The king and the lords have both sought to keep there a hold, by way of influence, so as to fight their

Government and Laws.

battle in that field always in the first instance, and thus procure an additional guard against the chances of more direct collision. The reform bill has to a certain degree stopped up the communications by which this arrangement had been in substance effected ever since, and, in fact, long previously to, the Revolution. Mr Hume remarks, on the existence of two legislative assemblies, separate from each other, yet each of them supreme, as one of the great anomalies of the Roman institutions. The characteristic danger of such a state of things exists also wherever the consent of two or more men is required in carrying on public business. The only difference is, that the danger in the latter case is often counterbalanced by greater advantages; and that the mischief will probably be less violent from their opposition in the passive shape of refusing to legislate in the same direction, than in the more active shape which their opposition might have assumed in Rome, that of positively legislating, one against another. It is evident, however, that a society, the elements of which, by the supposition, are not paralysed and torpid, must soon find out the means of evading the evils of a political stale-mate. The necessary unanimity can be only obtained by reciprocal compromises and forbearance. If we will have the benefits peculiar to such institutions, we must be content to pay the price. In the administration of justice, the limits which separate pertinacity and weakness is one of the difficult discretionary questions which judges and jurors have to settle with their respective colleagues. If every member of a jury or a senate were to be as impracticable as Cato is described to have been, institutions of this nature could in no country be allowed to last a week.

Mr Hume and Mr Bentham appear to agree in thinking, that in the case of numerous assemblies called upon to determine the much more extensive and variable questions which arise in the general conduct of political affairs, it would be unwise to rely upon the exercise of a similar discretion, as sufficient security for the analogous compromises which are nevertheless indispensable conditions to an efficient co-operation. For this purpose they both acknowledge the propriety of some species of influence, which shall make the one to a certain degree dependent upon the other. In such a case the only question which remains practically to be argued will be its nature and the mode and degree of its exercise. If Dr Paley gives too much countenance to influences approaching to a sordid bias, Mr Hallam, it may be feared, is somewhat too confident in the assurance that moral influences will of themselves always secure a just, or at least an adequate, concurrence.

Polybius has shown that the simple forms of government, however suited originally to this or that stage of society, necessarily become in time unsuitable. What he describes as the specific germ of decay, "congenite in each form," would be more properly described as an alteration in society itself. This alteration drags the government after it into the requisite modifications of its form. It is one of the great merits of a mixed government, that, without the violence of a revolution, it can accommodate itself to these changes in a community, and pass the initiative with comparative facility from one class to another, just as the leading shoot in society may happen to be making head. Under a nominal invariableness in the balance, some variance in the weights must always be going on. The crown was not easily content to resign the ascendency it once enjoyed. When the higher classes had to outward appearance ceded the political powers they had formerly possessed, they were enabled afterwards by circumstances to continue in the covert enjoyment of it, to a much greater extent and a much longer period than any one could beforehand have presumed. James I. probably was not aware of the tendency of the proclamation by which, on calling his first parliament, he directed the sheriffs to address the writs upon a principle substantially the same as the late reform bill. There can be no greater proof, on one hand, of the respect of the people of England for ancient forms, and, on the other, of the moderation by which the higher conciliated the jealousy of the middle classes, than the fact that the adoption of this principle was postponed during the next two hundred years. In those classes, including the gentry and independent commonalty of the realm, in whom for some time past the heart's blood of the country has mainly been formed, the reform bill has at last placed the command of the House of Commons. The power which this portion of the community before exercised indirectly over the whole parliament, and especially over that house, it now exercises directly. The consequence is, that there is a much greater security than before, that no measure detrimental to their interests, and in opposition to their feelings, will be agreed to by a House of Commons of which they are themselves now made the constituents. There need be no fear for the duration of moral frame-works like that of government, on the ground of their supposed analogy to the growth and decay of material forms. There seems also no better foundation for the inference drawn by Polybius, in his comparison between the governments of Carthage and of Rome as they existed at the time of the campaigns of Hannibal, where he says that a mixed government, in which the preponderance has passed from the monarchical and aristocratical to its popular members, has run its course, and is so much nearer to its termination. Difficulties enough remain inherent in the nature of all government, which no possible adjustment of the machinery can reach. But a mixed, though incomparably safer than a simple, government, has some difficulties peculiarly its own. It depends on a nicer balance of proportions, and it calls for a greater degree of temper, patience, and mutual concession from its members. A rational and public-spirited House of Commons must be in constant danger of offending one or other of the extreme parties in the state. Whilst its honest concurrence with the other branches of parliament must frequently incur the displeasure of the demagogue and his mob, the sovereign or the peerage, one or both, are often not unlikely to regard its general or particular opinions with equal jealousy. A constitution thus settled is only safe as long as the more intelligent part of society can take advantage of its intermediate position, and arbitrate between the extremes. A House of Commons, identified with the great arteries of the nation, contains within itself no inherent security for good government, beyond the power of stopping bad measures, and of sending good ones up for their acceptance to the other partners in the firm. If they accept, well; if they reject, a class of cases arises, on which all the good sense and good humour of a country may be wanted, in order to guide a people to discriminate aright on the course which it becomes them to pursue. Unless a power of rejection, according to a liberal construction of independent judgment, be conceded, the whole benefit of a second assembly will be altogether lost. The power of rejection may, however, be so exercised by a headstrong monarch or by a small hereditary body, especially when, in the case of the latter body, the greater part of the legislature have been recently raised to the peerage from the ranks of one political party only, as to amount to a declaration that they are looking only to themselves, their own interests and passions. A civil disseverance from the sympathies of the nation, like that of the Roman Catholic clergy, justifies the extreme remedy of removing the obstacle by whatever

Government and Laws.

means. The occurrence of such fatal obstinacy in the person of the sovereign, would be an exception to every presumption upon which hereditary monarchy is engrafted on a mixed government. The contingency of so remote and so insane a possibility could only be formally counteracted by some such expedient as is adopted with respect to the veto of the president of the United States. In the instance of a refractory House of Peers, the constitution has given the king the means of applying this remedy by a creation of additional peers. This course was taken by Queen Anne on a much more questionable occasion, namely, for the sake of a mere ministerial majority. It is not the less clear that a justifiable occasion might occur. If the king took courage to apply the constitutional remedy, all would proceed as usual. If he shrunk from it, the public would be remitted to those ultimate considerations of civil prudence which are always in reserve. They are the very same considerations which justify the sacrifices of natural liberty which men must make upon entering into a commonwealth. They may equally justify the sacrifice of social order which man is called upon to make whenever a commonwealth is overturned. It is to higher authorities than the precedents which are to be found in Rushworth, that freemen have recourse when they are compelled to seek new modes of legislation by forms which announce that the constitution has been destroyed.

The spirit and effect of institutions and of measures depend, as has been shown, in a great degree upon circumstances beyond themselves. The same institution at different periods produces very different results, whilst the collateral and unforeseen consequences of a measure are frequently much more considerable than the objects which its framers had in view. All that is most important in the present forms of the English constitution, is of a certainty to be traced, however obscurely and imperfectly, from a very early date. At the same time, it has become what it is, only by making the most of a series of fortunate contingencies. The English government may be advantageously compared with the Roman in its best characteristic, the tendency to progressive self-improvement. In the nature of the improvements there can be no comparison.

According to the process pursued, the substance has been in a course of much more extensive alteration than the forms. With regard to the latter, the change has chiefly consisted in removing partial impediments out of the way of certain movements, in strengthening particular springs to meet particular pressures, and in separating the several parts of the mechanism by more positive divisions, lest they should clash one with another. The manner in which the English clergy overreached themselves, by standing on their claim to exemption from temporal jurisdiction, and on their right to be taxed for temporal purposes, if at all, by themselves only, and in an assembly of their own, is very instructive and curious. They chose to remain apart, a separate estate; and resisted the attempt of Edward I. to incorporate the inferior clergy in the House of Commons, when that house as yet existed mainly for taxation. They procured their convocation about the same time instead of it. Afterwards, in its palmy state of general legislation, they discovered, when it was too late, that their exemption was turned into an exclusion. In 1663 the supreme head of the church of England found it no longer necessary to keep up appearances with a body already but a shadow. Without a law, a struggle, or even a word, convocations have died away. The clergy, on submitting to taxation by a temporal assembly, have acquired in return the humble privilege of voting for the members of a house in which they cannot sit. A few bishops in the upper house are all that remains in the English institutions, of that third estate which was so necessary a part of the diets and states-general of the continent, and which made so great a figure in our own original constitution. The suspension of the royal negative, and of ecclesiastical convocations, has, almost unobserved, become part of the modern English system. Yet the change which has been thus operated is far more important, though it is short of what it is sometimes represented, than many which have been the subject of fierce contentions, and introduced by the most deliberate enactments.

Legislature.

The transitions which we have hitherto been considering, are independent of and paramount to legislation. They follow slowly but necessarily the variations in the condition of society and in public opinion, which must decide nine tenths of the materials and spirit of every government. We proceed, therefore, to consider the principal alterations which positive legislation has successively effected in the three great divisions of political power.

The main objects of a government have been mentioned as being the making, interpreting, and executing the law; the first being the office of the legislature, the second that of the courts of justice, the third that of the executive administration. It will be proper to examine each shortly in detail, both as to its duties and its form. The English legislature, acting together as king, lords, and commons, is vastly too cumbersome to take upon itself the detail of the executive. This union, therefore, has never been thought of. Its incompetency either as a whole or in its parts to discharge judicial duties is not so soon perceived; consequently bills of attainder, of pains and penalties, and impeachments, are part of the legal history of the most recent times. In the infancy of courts of justice, and when the traditional supremacy of the *aula regis*, out of which both they and the legislature had emanated, was yet an active historical recollection, parliament in all extraordinary cases continued to claim an original judicial authority. But this pretension gradually dropped, and the appellate jurisdiction is now evidently near its close. Regarding the legislature in its legislative capacity only, it will be seen that its form has remained the same as a whole since the first admission of representatives from the commons. The changes which have taken place have been confined to the construction of its constituent parts, and to the view taken of the characteristic rights peculiar to each.

In considering the several members of the legislature, the king takes constitutionally the precedence. Nothing can be more superficial and incorrect than the view presented by Blackstone of early English history upon this part of the subject. It was not until the accession of Edward I. that the several titles of election, descent, and testament, on which the claims to the crown were before rested, as best served the occasion, became consolidated in that of hereditary descent. This appears to have taken place in analogy to the descent of land. The rival pretensions of the houses of York and Lancaster tended to throw the law once more into confusion. Being principally tried and determined upon the field of battle, the law had too much the appearance of giving way to force, or to its hollow consequence, a mere ostensible election. Yet, even in those times, there was no notion that the crown was left at the personal disposal of the monarch. William the Conqueror, it is true, had set up a donation from Edward the Confessor. But Richard II. on giving his signet to the Duke of Lancaster, as testifying his wish that the latter might succeed him, added, "but that did not depend upon his pleasure." The lords, in a remarkable lecture to the protector, the Duke of Gloucester, whose powers under the will of Henry V. had been limited by the parliament (for lords and commons are mentioned in the act), say his desire was grounded neither in precedent nor law; " the which the king that dead is, in his life, nor might by his last will, nor otherwise, alter without assent of the three estates, nor commit or grant to any person government or rule of this land longer than his life." The extraordinary provision of 28 Henry VIII. c. 7, is the first and only instance of putting the crown into settlement, with a remainder " to such persons as the king by letters patent, or last will and testament, should limit and appoint." It is plain that the testamentary power so granted to her father had puzzled men's minds in the time of Elizabeth: and that temporary authority to bequeath the crown has to answer for the strange and almost oriental scene by which the death-bed of that princess was disturbed. Since the Revolution, however, the parliamentary title is the one established in fact. Since the reign of Elizabeth it had been the only one recognised in law. The king never had a legislative initiative, but only a simple concurrence. The change of the form from petitions to bills, took away no right, but only an abusive advantage. The real legislative authority of the crown still continues in point of law the same that it has ever been. It was at no time more than at present, at no time less. The right to make law by proclamations, and the right to unmake it, whether by the repealing *dissimulavimus* of Edward III., or by a dispensing and suspending power, were always arbitrary usurpations. For these are utterly inconsistent with the principle, and almost with the letter, of the statute of Edward II., which had declared the assent of the lords and commons to be as necessary as that of the king; since the maxim that the same solemnity which bound is required also to unbind, is a rule of English law. The disuse of the royal negative since the reign of William III. is purely matter of discretion; however paramount the political necessity by which that discretion is determined.

The peerage was formed, under the feudal system, upon the principle of tenure, that is, of land held directly of the king; the mitigated sense in which the soil of the western world was understood to belong to the sovereign having been always very different from the absolute ownership of the sovereigns of the East. At the first, all tenants in chief had a right of summons to parliament, not yet known, however, by that name. During the period which elapsed between the demise of John, the last year of whose reign is remarkable for the division of the greater and lesser barons, and the middle of the reign of Richard II., when peers were first created by letters patent, tenure began to be disregarded. The political principle had so far got the better of the feudal, that in the 49th Edward III. the ancient writ of summons was changed from homage to ligeance. The further difference in the form of this appointment, as whether it was to be made by writ or patent, was of little consequence. But the dispensation from the necessity of holding land in chief was an important innovation. On the one hand, mere territorial possessions, distinct from descent, ceased to confer a title to a writ of summons; on the other, the writ in its general form might easily in time, by multiplying cases of dependent poverty, have turned this august assembly into the lacqueys of a court. It was well that a sense of dignity took the other course; though disfranchisements on account of poverty, as the act degrading the Duke of Bedford in the reign of Edward IV., and the resolution against Lord Ogle in the reign of Edward VI., were precedents liable to be abused. The questions, where the power of creating peers should be lodged, and the terms on which it should be exercised, were likely in early times to be determined by other circumstances than reason. The mode finally adopted, by which the power is intrusted to the sole discretion of the crown, appears to be, upon the whole, the most desirable. Yet the prerogative was so unsettled in practice, and probably also in law, that down to the reign of Henry VII. the assent of parliament was generally expressed in patents of personal creation. Upon this usage West founded his theory, in opposition to Prynne, that such assent was a necessary condition. Whatever may have been understood to be the law, the practice was liable to all the objections so triumphantly urged against the bill twice proposed by Lord Sunderland in the beginning of the last century, for limiting the number of the peerage. Whilst a restraint upon the royal prerogative of creating additional peers would occasion more evils than it could cure, no similar risk accompanies the withholding from the crown a power of punishing by exclusions or of privileging by exemptions the actual members of that body. Accordingly, Lord Coke holds that even dispensations, answering to the excuses formerly besought by poor boroughs, granted by the king in relief of lords petitioning to be spared the burdensome service of attendance, were contrary to law. The mode in which the prerogative of creation was exercised varied with the times, but never seems to have been felt to be a grievance. The jealousy of the Stuart creations before the breaking out of the civil wars, and the remonstrance against the Scotch and Irish honours, was only a temporary ebullition. The degradation which the decay of families might have brought upon so much of the peerage as was called by a general writ of summons, came to a certain degree within the control of two principles: the one, that a patent without words of inheritance is simply a dignity for life; and the other, that peers might be summoned only to a single parliament. There are instances of ninety-eight laymen who were summoned only once, of fifty others who were summoned two, three, or four times. The present course, however, of descendible nobility, is as old as the reign of Elizabeth. The uniformity of our modern usage would be corroborated, amongst other causes, by the contemporary extinction of a corresponding variation which had previously subsisted in the summons of the ecclesiastical members of the House of Lords. The bishops are said to sit by a usage compounded of a triple title. They are supposed to be the representatives of the church, to have been more learned counsellors than the lay nobility, and to be the life-proprietors of the baronies attached to their sees. The last condition, however, is wanting in the sees erected by Henry VIII. But parliamentary bishops formed a small portion of the spirituality in the upper house. Out of one hundred and twenty-two abbots and forty-one priors, who occasionally sat previously to the dissolution of the monasteries, it appears that only twenty-five abbots and two priors were constantly summoned. There are numerous instances of the allowance of exemptions to abbots and priors after summons, by reason of their holding nothing of the king. This ground of exemption, as insisted on and admitted, shows *whence* the duty was derived. It does not follow but that the grounds of *right* on their part might be more extensive. It is according to this distinction that the writ requiring the attendance of the temporal nobility by summons, belongs to a period and style when its duties were an *obligation*, and were recognised as such; the patent to a period when they had become an *honour*. The most important parliamentary change, however, which collaterally resulted from the dissolution of the monasteries, was the subordinate condition to which it reduced the church numerically in the House of Lords. This alteration was likely to diminish the general political influence of the church much more than the subsequent cesser of the convocation in 1663.

The authority of the convocation being confined to the clergy, the public at large had little immediate interest in its operations beyond the share which they might therein please to assess themselves by way of ecclesiastical contribution towards the public burdens. In point of fact, the temporalities even of the church seem to have lost nothing from either cause; much less its substantial influence. Few will think, whilst the clergy have been shut out from the commons, and lowered down to the compliment of a single bench amongst the lords, that their friends have not done for them behind their backs quite as much as they could have done for themselves if present. The influence of the church of England in its apparently almost unrepresented and unprotected state, is a great proof how little comparatively depends on the means by which an end is to be produced, when a power, composed of a wealth, an intelligence, and an opinion competent to produce the end, is really in existence out of doors. Although the dignitaries of the Roman Catholic church varied in numbers from time to time, yet they always formed the actual majority of the House of Lords up to the Reformation, which, nevertheless, they could not stop. Here, again, with what prudent reserve did the Roman Catholic clergy husband for ages the political power which mere numbers vested in their hands; and how evident is it that, whatever form, even of superstitious incarnation, the dominant spirit of a government may assume, it is only by compromises that it can subsist. The Stuarts, the great examples of every species of political misrule, would have been ruined by this alone; they were bent on acting up to the very extent and margin of their powers. Nobody reading English history previously to the Reformation would have an idea that during all that time the temporal nobility were in a minority; that therefore their legislative importance existed only by permission; and that every act of the House of Lords might be said to be in strictness the will and pleasure of the church.

The number of the lay nobility has fluctuated considerably. It had advanced from fifty-five in the reign of Henry VIII. to one hundred and six in that of James I. It is at present three hundred and ninety-one. The aristocratical complaint made by Lord Delamere under James II. that, ever since the time of Henry VII., a systematic project had been pursued to humble the peerage, by means of multiplying its numbers, and by introducing into it persons of mean extraction, was particularly injudicious. Unless something of this kind had taken place, the extreme disproportion between the two houses, in their external as well as in their personal titles to consideration, would have deprived the peerage of a great part of its present strength. If the order was to be more than a pageant, it became most desirable to increase its numbers to the extent of giving them a better chance of bearing some comparison in ability and character with the select representatives of the rest of the nation. It was scarcely less so to recruit into their ranks those members of the commonalty who, whatever might be the obscurity of their pedigree, were most distinguished for their wealth or services. Thus alone could the body have been protected against the narrow sense of corporate pretension which must otherwise have infected it. The long recollections which feudalism has left, and the recent jealousy which has collected around corporations, notwithstanding their former usefulness, demonstrate the depth of the national re-action, which all invidious exclusiveness unavoidably provokes. In fact, no amount of popular opinions has been sufficient to save the combination of the great Whig families from a suspicion of aristocratical tendencies of this description. The popular criticisms on the corn-law legislation of landed proprietors are a proof of the keenness which watches every supposed connection between public policy and partial interests. An evil not quite similar, but equally, indeed in all probability more, destructive in its consequences to the object and safety of the peerage as a branch of the legislature, must follow, whenever its vacancies are too long filled up from a particular party in the state. It is self-evident that the chances of a difference of opinion between a House of Lords partially constructed, and a popular House of Commons, cannot be raised with impunity beyond a certain point. Under the most accurately-balanced government, the question, whether the Lords shall at any time interpose their legislative negative, must of course, as in the case of the king, depend at last on their own discretion. The difference in practice is found in their respective positions. There can scarcely remain a possible presumption in favour of the single opinion of a chief hereditary magistrate, when a majority of the nation, aware of that opinion, is found constitutionally ranged against him. On the other hand, abuse in their original appointments, and ignorance of the duties and necessities of their station, must have gone to an extravagant length indeed before a body of the nature of the House of Lords is put in equal peril by the rejection of whatever measures may be sent up to it by a majority of the House of Commons. Take either extreme; a House of Lords in constant collision with the Commons, or a House of Lords only occupied in registering its edicts. In the former case, it cannot exist long; in the latter, it is already existing only in name.

The popular part of the English constitution is lodged in the House of Commons, which originated in the year 1295; and, in its present extension, consists of the representatives of different interests or sections of the community, by individuals of their choice. It is very singular that the simple expedient of popular representation, an indispensable condition to every form of a free government in a great kingdom, never occurred to the legislators of antiquity. By this device, the experiment of a free government is entirely changed, and becomes, under all circumstances, infinitely more practicable, safe, and beneficial. According to the ordinary theory of the English constitution, the House of Commons is said to represent the whole population, as far as it is supposed to be by its circumstances independent. Of these, the knights, or the members returned by the freeholders of the county, are alleged to represent the interest concerned in agriculture; whilst the citizens and burgesses, or the members returned by certain towns, have been described as representing the interest concerned in trade. The basis of English representation, at first very limited, and long extremely fluctuating, was never so extensive as to answer to the first part of this theory; and time rendered it, by the rise of some places and the fall of others, still less so. The reform bill has probably more nearly approximated towards realizing the theory of a representation as universal as the independence and intelligence of the people, at the present than at any former period. The most that can be said of the latter proposition is, that some such division as it assumes between real and personal property, agriculture and trade, probably appeared originally between the two classes of members. This was the natural course as long as the duty of the House of Commons was confined to taxation. The original demarcation would probably continue visible as long as parliamentary attendance was considered as a burden rather than an honour. Historically, this and any similar distinction gradually fell into disuse soon after the 23d Henry VI. That statute required the knights of the shire to be actual knights, or such notable esquires and gentlemen (*generosi a nativitate*) as had estates sufficient to be knights, and by no means of the degree of yeomen. We find that a county member who had been actually elected, was set aside because he was not of gentle birth. A great change must be commencing before the possibility of the want of such a precaution could be suggested; and still more before the precaution, when taken, should not immediately succeed. The change may be assumed to have begun as far back as the 19th Edward II. when there were twenty-eight county members who appear not to have been knights. Of course the arrangements and very elements of society must have been still further broken up, before a manufacturer could have a chance of a successful nomination with the freeholders of a county court. It is but little that positive legislation upon these points either accelerates or retards. It can recall nothing; and, to be effectual, must continue to be in harmony with the wants and character of the times. This was abundantly proved in the failure of the statute of Henry V. the object of which was to compel members to be inhabitants of the places for which they served. The attempt fixes the era when the deviation from the old connection was attracting general attention. Its pertinacious vitality in the statute-book is a striking instance also of the extreme reluctance with which the English people, so far from anticipating needless innovations, have consented to affirm the innovations made by time itself. Prynne shows that Cornish names were formerly returned in the elections for Cornwall, and northern from the north. Clarendon opens his memoirs by stating the little communication which passed between different parts of the country, even with the metropolis, almost to his own time, except in the circuits of the lawyers. The names of the members for the counties were aristocratical, those for the boroughs plebeian. A few burgesses begin to be called esquires in the returns of Edward IV. By this time the House of Commons was becoming of sufficient importance to render parliamentary influence with a borough an object of ambition to the nobility and gentry of its neighbourhood. The character of the borough representation opened and extended itself accordingly. It soon embraced every description of person who had a claim to enter into public life. The lawyers, to whom attendance was probably less personally inconvenient than to others, appear to have come in earlier for more than their reasonable share. But this expansion and adaptation beyond its original purpose could alone have made the inequalities and anomalies of the borough representation tolerated so long. The citizens and burgesses, though always more numerous, seem to have felt their social inferiority, and for a long time to have continued more humble minded than the knights. Of the three hundred members, the average number from the 23d Edward I. to Henry VIII., a third or more were returned by the boroughs. During this long interval the sheriff exercised a discretion, to the use or frequently to the abuse of which the parliamentary existence, by prescription, of many unincorporated boroughs is to be ascribed. Boroughs by charter, even from mesne lords, and towns, whether the ancient or the actual demesne of the crown, made up the list. Many boroughs were originally inconsiderable places; and others imperceptibly decayed. This latter cause would take effect from the reign of Henry VIII., the date at which the elective franchise became constitutionally too valuable to be left, when it had been once enjoyed, to the mercy of the sheriff, or to be allowed by its possessors to drop into disuse. The royal prerogative of new creations which existed in the House of Lords, existed also over the borough compartment of the House of Commons. Elizabeth indulged herself in the plenary exercise of it in England, as freely as her successor did in Ireland; but, supposing that her subjects had ventured to remonstrate, she was too wise to have ventured, in return, on his indecent answer; "The more the merrier, the fewer the better cheer." The prerogative of adding to the boroughs, however, is one which could not last in an enlightened age. The same reasoning which pleads against a parliamentary or popular appointment of the peerage, presumes a parliamentary or popular appointment of the commons. It is not so surprising, that after the shaking up of the political opinions of the nation during the civil wars, one instance only of borough creation (that of Newark) should have occurred, as that Charles II. should have made the experiment even of one. Borough creations were the great reservoir whence the successive accessions to the numbers of the House of Commons had been supplied. Nevertheless, owing to the course pursued previously to the passing of the reform bill, the interests engaged in commerce and manufactures appear, notwithstanding the vast contemporary augmentation of their wealth, to have had less power in parliament, or at least less influence on legislation, than in an earlier age. The House of Commons in the first parliament of James I. consisted of 470 members. The last unreformed and the present reformed representation, reckoning the additions derived from the Scotch and Irish unions, are not much more numerous. They both give a total of 658. The difference between the two lies in the proportions in which these numbers are divided amongst the several classes of the people. It has been calculated that a hundred and fifty-four persons returned a majority of the former house. Counties formed the only large constituencies, whilst scarcely a single large town was represented. At present the franchise is compounded of a ratio of property and numbers. Mere nomination is destroyed; and, on analysing the numbers, it will be seen that the members for counties are 252, the members for towns and the universities 406. This question of proportion, though it has been assumed by critical writers, was evidently never before seriously thought of. The necessity of entering on such comparisons had not yet arrived. The means of securing the impartiality of the sheriff, and the independence of the electors, was formerly a more immediate and important point. It is impossible, from the gross partiality of the sheriffs (officers annually appointed by the crown), to reason upon the old returns. The freeholders of a county court were of course placed comparatively beyond their reach; yet sheriffs contrived to aid in the virtual disfranchisement even of counties. According to Prynne, it appears by the indentures that, as late as the 8th of Henry VI. the attorneys of a few great people could dictate or manage on occasion the representation of Yorkshire itself. In the meanwhile political information was spreading. Reformers of all kinds sallied forth. The decayed boroughs, and the consequent flagrant inequality of representation, became the subject of a criticism, founded on theories more or less correctly derived from the practice of earlier times. The very word representation provoked observation, and was in many instances in ridiculous contradiction with the fact. It appeared impossible that this could be what the constitution intended by the name. Even James I. was struck by it on his accession. The charge given by him to the sheriffs, on calling his first parliament, not to direct a writ to any ancient town, being so ruined that there were not such sufficient residents as to make a proper choice, comprehended a most desirable reform. The fault was in the mode which he proposed for carrying it into effect. The supposed prerogative was more than could be safely entrusted to a sheriff of James I. The system grew more unreasonable every day, both in reality and in appearance; and, to complete its indefensibleness, the stain of corruption gradually crept in, and deepened the offensive spectacle into a scandal and a nuisance. The reform bill has at last brought this long outstanding grievance to a satisfactory conclusion. The elective basis is so enlarged as to comprehend all the elements of sound national self-government, and the independence of the electors is amply secured against all danger but from themselves. The interference of the executive in elections may be more immediately dangerous to freedom; but a constitution undermined by corruption is infinitely more disgraceful to the parties who are guilty of it, and to their fellow-countrymen, who sit still in stupid connivance at their baseness. Lord Coke, mentioning the first case of bribery on record (in the 13th Elizabeth), denounces it "as poisoning the very fountain itself." The disease was communicated slowly. It is not yet a hundred years since it had reached the height and notoriety of being a public evil and a national dishonour. Clarendon, in his disdainful notice of the first ministerial intrigue in order to buy over a majority by bargaining and not by reasoning, leads us back to the origin and cause of all. He fastens on the government the first link of the chain, the length and burden of which naturally increased at every remove. Bolingbroke, the distinguished father of the modern Tories, lays the principal blame of it on Clifford. Members who could make money of their own votes, found it was worth while to pay for the votes of their constituents. Evelyn's *Memoirs* contain frequent ejaculations on the increasing expense and debauchery of elections, before and after the Revolution. In works of the date of Brown's *Estimate* and Chesterfield's *Letters*, it is noticed, for the first time, that the franchise of making laws for the English people was disposed of by boroughmongers under private pecuniary contract, or brought openly to market by burgesses and freemen, for the competition of public sale. The expense of elections, to say nothing of bribery, had become so ruinous, even in the earlier days of Burke, that in a speech on one of Mr Sawbridge's motions, he says, "the expense of the last election has been computed (and I am persuaded that it has not been overrated) at L.1,500,000—three shillings in the pound more than the land tax."

The antiquarian question of the origin and progress of the House of Commons is interesting, not merely as the title-deeds to English freedom, but as constituting an important chapter in the history of man and of society. It describes the germ and development of an institution which, in its extensive and permanent application, is an invention of modern times, and the most likely of all, not even excepting the steam-engine and the press, to influence the fortunes of the human race. In this view, the great consideration is not so much the steps by which its component parts were formed, as those by which its authority was obtained. There can be no doubt that the early summons to the commons was not honorary, but onerous. Long after the general right was perceived to be a national advantage, the particular exercise of it was felt to be an individual hardship. The real history of almost every people is in its exchequer. This is emphatically the case with England. Fiscal considerations lie at the bottom of its most celebrated institutions and enactments. Every body worth taxing was to be got at in some form or other. The right of arbitrary tallage upon towns was limited and invidious. It was abolished in the 25th Edward I. by the time that the new experiment was coming fairly into play. In the facilities which representation afforded to taxation, government soon found a compensation for the slight additional control and inconvenience which the co-optation of the commons into the legislature might by degrees and at times occasion. The yeomen owners of freehold lands were to give an account of their pecuniary capabilities in that character. Wherever property had grown up in other shapes, as in towns, it was also to be made amenable. Apparently when this was done by way of deputies, which was the ordinary mode in the estates and diets of the middle ages, no particular directions issued. There is not a word said in the writs concerning the qualifications of the electors, or the numbers to be elected, or the forms to be observed, either in counties or in boroughs. Two was the number fixed upon, probably to prevent subsequent confusion, either by prevarication, mistake, or sickness; and usage would soon turn the practice into law. Whilst taxation was the great object at stake, it was one in which all might equally be trusted for labouring to reduce the subsidy to the lowest point. The franchise in boroughs would easily devolve from the towns' people at large to a select council, when all that the voter got by insisting on the privilege, was a liability to pay his share towards the parliamentary wages of the member. The election struggles of a later age, indeed ever since the committee of which Serjeant Glanville was the chairman, have been vain efforts to undo the effect of these irregularities and encroachments. But the great objects of a national legislation and the spirit of freedom were of older date. Long before the actual existence of the commons as a third estate in parliament, the barons had extorted from their monarch, and had transcribed into the rude articles of Magna Charta, a principle and a feeling, before which the traditional longings after the laws of Edward the Confessor speedily expired. There was little left for the patriots of after times to add, but the necessary machinery of more adequate forms and institutions. Magna Charta seems to have been looked upon almost as a personal contract, which it was necessary to renew at the commencement of every reign, in order to make it binding upon successive sovereigns. The terms of its successive confirmations (Lord Coke reckons no less than thirty-two) fixed in the minds of men an inseparable connection between the grant of supplies and the redress of grievances. The House of Commons put forth at different periods the claim to its peculiar privileges and its general powers. As early as the reigns of Richard II. and Henry VI., we find it refusing to proceed in the public business without a sufficient answer. For a time the two houses voted separate and unequal aids. The first notice of the maxim that parliamentary aids must be granted by the commons and agreed to by the lords, appears in the 9th Henry IV. As the report expresses it, when both are of accord, the grant is to be signified to the king by the mouth of the speaker of the House of Commons. This is said to be "in manner and form accustomed, to the end that the lords and commons may have what they desire of the king." The strictness of this privilege can never have stood on any sufficient reason. It was unimportant whilst the two houses voted their subsidies singly, and bound each other to different amounts, which continued to be the course with the clergy in convocation to the last. It was still more indifferent which of the two began from the time that supplies were voted by them in concurrence, since either house, by the use of its negative, could protect itself. Restraints on the initiative are not worth contending for. The exclusive right of determining all questions connected with the elective franchise would have been a more equitable distinction. Upwards of a quarter of a century before the third estate was called to parliament, the barons had paid the subsidy demanded of them into the hands of four of their own order, with directions to expend it at their discretion for the benefit of the king and kingdom. It was not until after the Restoration that the House of Commons was provoked, by the scandals of the court of Charles II. to adopt the much more respectful form in use at present, for the control and appropria-

Government and Laws.

tion of the national expenditure, although Clarendon declaims against it as an unheard of innovation. Of all their civil rights, immunity from taxation, except through parliament, has been that of which the English people were most tender, and which they first succeeded in thoroughly and irrevocably establishing. After the reign of Edward III. a few attempts, ill concealed under the soft words of loans and benevolences, are slight exceptions to the universal current of precedents. On this, admitted by Clarendon to be the clearest of all points, the Stuarts dragged the judges with them into the abyss. The patience and perseverance of the English people are equally signalized in the steady parliamentary resistance by which the account of ages was closed with the act of the 16th Charles I. c. 8, against the imposition of tonnage and poundage, without consent of parliament. It is the last act in the statute-book against arbitrary exactions of revenue. The right to participate equally in general legislation was obtained early, but slowly enforced. The 15th Edward II. had recognised the necessity of the concurrence of the commons to all measures whatever in the most positive terms. It is probable, however, that for some time afterwards, its assent for all purposes except taxation was little more than constructive. The commons, it is true, after the next reign, figure, by name at least, almost always in the enacting clauses; the laws being generally said to be made by the king, with the assent of the lords, at their request. At this period, however, the king, by diminutions and additions to a petition, often so completely changed its nature, as to become himself the real legislator on its contents. They consequently insisted, in the 2d Henry V. "considering they had ever been as well assenters as petitioners," that without their assent it should be no statute. The abuse was only put an end to in the reign of Henry VI. by the slight variation of drawing up the bills in their present form. There is only one instance mentioned during the tyranny of Henry VIII. of the rejection of a bill supported by the crown. The commons found courage on several occasions to resist the measures of his children. The year 9 Henry IV. above referred to, is also remarkable for the first assertion in behalf of freedom of speech in parliament, by declaring that the king is to take no notice of what passes there. This impunity is confined, however, to the locality of the speech so spoken. A publication of it by the press or otherwise is responsible to the ordinary law. The earliest definition of privilege on arrest is in Larke's case, in 8 Henry VI. The case of Storie in the 4th Edward VI. is the first commitment which has been recorded of one of their own body for contempt. In proportion as the House of Commons became gradually more and more mixed up with the general affairs of state, the possession of these powers and privileges rose in importance, as being essential to its independence. Mere assurances of this or that immunity are of no avail, unless the means of realizing them also exist. The necessity to which Sir Thomas More was obliged to yield, of retiring into private life, in order to escape the displeasure of Henry VII., on account of a speech in the House of Commons, shows that the season for a valid parliamentary opposition had not yet arrived. In the attack upon the five members in the house itself, Charles I. outheroded himself. On other occasions, he had lain in wait for the dissolution of parliament, which was his usual signal for resuming more open hostilities against the liberties of his people. As soon as the speaker's mace had been disenchanted of its protecting power, the royal warrant was wont to go forth against the most popular of the late members by whom his illegal designs had been principally thwarted. The law and the fact, however, improved together. Both houses have long been in possession of whatever powers can be necessary for the performance of their public duties. Popular members are as safe after as during sessions. Nobody dreams of intimidation. Parliamentary corruption has not merely declined; it has almost disappeared. If a comparison between the pensioners and placemen of ancient parliaments, with the modest list of officers of the crown sitting there at present, be satisfactory, what ought to be felt at the contrast between the unblushing bribery of Walpole's administration and the purity of modern governments? The compulsory economy introduced into the treasury has co-operated, with other causes, of which the chief is public opinion raised under the sanction of the middle classes, to elevate the standard of public morals amongst public men. The boundary which separates legitimate and undue influence, is that at which practical politicians no less than theoretical reasoners have arrived at last. As corruption began at the top, it has first ceased there. Whatever remained to be done in improving the public spirit of the elected, as well as of the electors, it is the direct tendency of the reform bill to accomplish. The elective franchise is now thoroughly identified with the nation, and is made, in the eyes both of those who choose and those who are chosen, more visibly and entirely a public trust. The destruction of the nomination boroughs leaves no pretence for the open constituencies which persevere in converting the trust into a sordid personal advantage. The parts which unfortunately appear to continue tainted are as yet inconsiderable. Unless they yield to the alteratives by which the whole body politic has been renewed and strengthened, they must be cut out. History holds out no hope that the inconsistency of incorrupt representatives and of corrupt electors can continue long.

Govern- ment and Laws.

The supposition of a legislature consisting of three coordinate authorities, does not imply a defined line or logical division to which they must each conform, and which every body can distinguish; on one side of which, the concurrence of the several parts must degenerate into mere dependence; whilst, on the other, their separation must form into impracticable opposition. The experience, however, of all mixed governments, more especially a comparison of the case of England with that of countries subject to the simple forms, establishes the fact that it is not a mere fiction, concealing under nominal distinctions the real servility of the inferior in their subjection to the superior members of the supposed partnership. It is evident that a sort of adjustment does practically take place, sufficient to produce a palpable effect. The nature and temper of a particular society may easily make such a constitution impracticable. But, under fortunate circumstances, it in a great measure accomplishes the ends which it is its professed object to perform. The problem assumes the natural inclination of its respective parts to press unduly on each other. In tracing a constitution which has been formed by time, and has endured through ages, the tendency of the several biases must be expected to be more apparent, now one way, now another, than in a government of entirely new construction. Encroachments at different periods are more likely to take place, from a recurrence to former usages on one side, or from a spirit of re-action to them on the other, in constitutions which have grown up, like those of England and ancient Rome, by the amendments of centuries, than in mechanical contrivances, like the government of Lycurgus and that of America, modelled from the beginning and at once, on an express design. Accordingly, English history presents examples of each branch of the legislature in its turn assuming a legislative power. The king has issued his proclamations to create, not to promulgate law, under the pretence of state expediency. An irregular exercise of the equivalent power of suspending or dispensing with the law, in other words, a claim to untie by himself the knot which the entire legislature had tied, had prevailed so long, that even at the Revolution it was only partially denounced. Ordinances authorized by both houses, whether for the militia or otherwise, are equally indefensible. The same is the case *a fortiori* with resolutions by either house singly against putting in execution such laws as happen to be unacceptable to it, but which the other branches of the legislature are not willing to repeal. Notwithstanding a most unguarded admission by Mr Justice Gould to the contrary, in the conflicting decisions which arose out of Wilkes's case, there can be no doubt but that the doctrine of Lord Mansfield is correct. Speaking of declarations of law made by either house of parliament, he observed, that he never thought himself bound in his judicial capacity to honour them with the least regard. The vote of the commons in 1648, that their single enactment was law, called forth on the Restoration the statute of 13 Charles II. It subjects to the penalties of *præmunire*, the advised affirmation that both or either of the houses of parliament have any legislative authority without the king. The unconstitutional attempts of both houses, especially of the lords, to extend their jurisdiction as courts of justice, brings us properly to the next consideration.

Judicial power.

The necessity of separating the judicial from both the legislative and the executive power, and of vesting it in independent tribunals, is now universally admitted. But it is a necessity which antiquity never perceived; and it was in direct opposition to the letter and the spirit of the feudal system. Therefore the successive generations which moulded the English constitution into shape, may be excused for having learned it but slowly and by experience. English history providentially is stained with fewer judicial iniquities, which are the greatest of all crimes, than that of almost any other country. But a failure of justice is the worst feature of the long period comprehended in the lines of Plantagenet and Tudor. Perhaps the greater part of the deficiency is to be attributed to the imperfect division of these powers, especially of the executive and judicial. Lord Clarendon has left a picture, sketched as late as the middle of the reign of Charles I., of what may be expected from a legislature, a court of justice, and a board of administration, all in one. Officers of the crown became " a court of law to determine civil right, and a court of revenue to enrich the treasury; the council table by proclamations enjoining to the people that which was not enjoined by the laws, and prohibiting that which was not prohibited; and the star-chamber, which consisted of the same persons in different rooms, censuring the breach and disobedience of those proclamations by very great fines, imprisonments, and corporal severities; so that any disrespect to any acts of state, or to the persons of statesmen, was in no time more penal, and the foundations of right never more in danger to be destroyed." The supreme courts at Westminster were originally derived out of the royal court or *aula regis*, which consisted of the great household or personal officers and the barons. They were intended to dispatch the ordinary judicial business, especially during the absence of the household and personal officers in attendance on the king, or when the barony might not be assembled. The authority of these derivative courts, whatever might be the case with the *aula regis* as far as concerned the barons, was not in the eye of the law inherent. It was supposed to be delegated to them by the king, as the fountain of justice to his subjects. The judicial power of parliament, however, was not displaced, nor meant to be so, by these auxiliary institutions. Fleta, writing in the reign of Edward I. treats it as still the high court of justice, " where doubtful cases of judgments are resolved." There can be no doubt but that annual parliaments were first demanded, and their intermission felt to be a much more serious grievance on account of their judicial than of their legislative capacity. It is evident, from the state of the early statute-book, that the meeting of many a parliament might have been saved had they met only for the purpose of legislation. There is a memorable order of 18 Edward I., by which petitioners to parliament are apportioned to the several subordinate courts of justice, both for their own dispatch, and to enable parliament to attend to public business. If the matter happened to be so great or of such grace that these courts could not end it, the chancellor and chief ministers were with their own hands to bring it before the king and his council. Coke observes, that wherever the king and council are mentioned judicially, it is to be interpreted to mean the House of Lords. The celebrated treason statute, 25 Edward III. closes its enumeration of the treasons specified therein with the express reservation of " other like cases of treason which may happen in time to come." In which case " the judge shall tarry without going to judgment of the treason till the cause be showed and declared before the king and his parliament, whether it ought to be judged treason or other felony." The reservation, however inconsistent with the right of a people that the law shall be defined beforehand, so that they may know what to avoid, and under what penalties, is plainly a reservation of judicial and not of legislative power. In fact, this parliamentary superintendence is recorded, on the authority of Chief Justice Thorpe, to have been at that time the common course in other cases as well as treason. He stated, in the 40th Edward III. " that he and Sir Hugh Green went together to the parliament, when there were present at least twenty-four bishops and earls, and asked the opinion of those who had been the makers of the late statute of jeofail, concerning the alteration of a record." " At another time," the same judge says, " we were commanded by the council, that when any case of doubt should happen, we should not go to judgment without good advice; therefore," adds he, in the case then before the court, " go to the parliament, and as they will have us do we will, otherwise not." The danger from this anomalous tribunal would have been increased a thousand fold, if the lords had succeeded in the unwarrantable claim which they set up in 11 Richard II. to a law of parliament differing from the civil and the common law. The extension of this irregular claim by Coke to the privileges of the lower house was more, certainly, than the imperious barons of Richard II. ever contemplated by their mutinous declaration. But it is still more unwarrantable, and more surprising, that Burke should have renewed the doctrine of a parliamentary supremacy, in judicial proceedings before parliament, over the rules of ordinary law. As the penalty of this grievous error, his admirable Report on the proceedings against Warren Hastings remains comparatively unknown.

The share which the House of Commons took in this judicial jurisdiction was, if any, very inconsiderable. Thorpe in the above passage uses the word parliament, but mentions only earls and barons. The ordinance 6 Henry IV., which has provoked so much legal spleen, from its directing that no apprentice or other man of the law should be elected a knight of the shire, took its hint from a previous one in the reign of Edward III. against lawyers practising in the king's court. They were accused of putting forward, as public petitions of the commons, matters which concerned only their own clients. Notwithstanding the expression client, the ground of disqualification here assigned relates probably to what was formally legislative, and not judicial business, something like the private bills of the present day. From the course of the constitution, as well as on their own disclaimer, Mr Hallam considers that the intermeddling at all in judicature by the commons upon the petitions addressed to them, was pure usurpation. He suggests that their intrusion may probably account for the disuse into which, from the time of Henry IV. the lords allowed their appellate authority to fall. It is very difficult to make out the steps by which they could have claimed the right in question. But there is some difficulty in conceiving that the influence of the House of Commons was so commanding at the period in question as the alternative supposition would imply. Could they be strong enough to make good a mere encroachment of this sort, and leave a competitor like the House of Lords no other method of resisting their invasion of its ancient right than by also abandoning it altogether? Writs of error were resumed by the lords about the accession of James I., renouncing all claim to any original jurisdiction in judicial causes. This is surely anomaly enough. All pretence for the other had disappeared in the equality of persons, in the uniform supremacy of the law, and in the acknowledged excellence of the ordinary tribunals. Notwithstanding this disclaimer, the extent to which the English legislature, under circumstances more or less excusable, perplexes itself with questions properly belonging to courts of justice, is subject to serious objections. It nowhere appears to such disadvantage as in bills of attainder, of pains and penalties, and divorce bills, which are all proceedings of a judicial nature applied to a case of *ex post facto* law. In judicial inquiries, carried on as such by either house, its numbers, partialities, habits, and the intrinsic difference between legislative and judicial considerations, make it impossible to convert a legislative assembly into a satisfactory court of justice. This truth has been frequently, and is still, occasionally verified. In its character of a court of ultimate appeal, the House of Lords escapes the disgrace which must otherwise have been heaped upon it long ago, by retaining the jurisdiction only in name, whilst the jurisdiction is in fact abandoned to its legal members. There is more to be said for so peculiar an exception as that of an impeachment. But later precedents, as in the instance of Warren Hastings and Lord Melville, do not warrant the expectation that an impeachment, even before such a body, can easily become an efficient instrument of justice. The only judicial matters which can be brought before the House of Commons are proceedings for contempts. Hurried on under great excitement before the whole house, they are exposed in an aggravated shape to whatever risk proverbially disqualifies an individual from being a judge in his own cause. It is only in comparison with what is recorded of the trial of disputed elections by the house itself, that election committees have acquired a conditional reputation. Committees on private bills are frequently legislative only in form, whilst they are in reality judicial inquests. They consider themselves above even the forms of justice. Nothing is more common than for members to oblige their friends, by stepping in to divide upon the merits of a case, where they have never heard a syllable of either the evidence or the discussion. It is a singular instance of the force of habit, and of the barrier raised by technical distinctions, that this is done by persons who would act nevertheless with perfect honour upon a jury.

In a simple state of society the judicial and executive authorities are always found united. Eastern kings administered justice at the gate; St Louis under the oak. A confusion between these authorities is therefore, under all governments, in the natural course of things a more probable event. The original theory of the English constitution, as far as theory can be predicated of its rude provisions, saw no incongruity between the duties. The traces of an entirely opposite presumption are still amongst the minor embarrassments of at least the language of the law. The administration of justice in the name of the king was formerly more than an honorary prerogative. It was a feudal truth and necessity. It is now a fiction which can only mislead both kings and people. Blackstone says, that when the law calls the king the fountain of justice, it does not mean that he is the author of it, but the distributor. Yet there are many things contrary to this distinction, and the contradictions show most strongly the mischief of these metaphorical compliments. The payment of fees on original writs, the unjust rules in the exchequer in behalf of the prerogative, the flagrant fines in the olden time as the only means of obtaining common justice, presuppose that the king was so far its author that he could only be asked to grant it upon his own terms. Judicial extortions became less frequent after Magna Charta; but they prove the grievous necessity which existed for its assurance that the subject should have remedial justice, "freely without sale, fully without any denial, and speedily without delay." A tax on justice is one of the worst sources of royal revenue, under whatever title it be imposed. At the present day the propriety of completely separating executive and judicial duties is the tritest truism. It is next to impossible that a sovereign should have the leisure, the attainment, or, in the most important cases, the impartiality, to administer justice in his own person. The guilt of tampering or of intimidation addressed to the judges, to whom the king has on the part of society committed his judicial trust, is a heinous offence in the meanest subject. When it proceeds from the king it is aggravated a thousand fold. But it is not enough that the hands of justice should be pure. Their purity should be beyond suspicion. For this purpose the independence of the bench ought to be maintained above all possibility of fear or favour. Perhaps there is no better evidence of what had long been only tradition concerning the personal attendance of the king in his courts of justice, and on the limits within which he was confined, than is contained in the case of jurisdiction of the House of Peers in the year 1666. It is there said, that "when the king attends in the House of Lords in his judicial capacity, he sits but as chief justice, doing nothing singly, but by plurality of opinions, as when the kings would in person sit in the king's bench, which they have in former time done, where all is said to be *coram rege*, though now he never come there; and in our memory King James hath sate in the star-chamber." It is natural that the king's presence should be last seen in the courts, which were not made unintelligible to common understandings by the forms of the common law, and which, by retaining the longest the name and the character of his council, seemed to keep the nearest to his person. Serjeant, when elected speaker in 1640, tells Charles I. "My disabilities are best known to myself; and to your majesty, I suppose, not altogether unknown; before whom, in the course of my practice and profession, it hath been your goodness towards the meanest of your subjects divers times to do me the honour and favour to appear and bear a part as an ordinary pleader." So little did the Plantagenet generation know what they ought to have prayed for on this subject, that in a list of very bold articles presented by parliament, to which Henry IV. consented in the eighth year of his reign, there is found the following request. It was prayed his majesty, that, "considering the wise government of other Christian princes, and conforming himself thereto, he would assign two days in the week for petitions, it being an honourable and necessary thing that his lieges who desired to petition him should be heard." James I. had a great longing to exhibit every phasis of his learning to his subjects. After having been told in Wraynham's case by the judges, *cessat regnare qui cessat judicare*, it is not surprising that he should think the opinion of Lord Coke, that kings of England were incapacitated from the exercise of any judicial functions, little short of treason. Nothing, however, is more fully settled than that, as on one hand, the House of Lords, the Privy Council, and the ordinary tribunals of the common law, derive all their judicial authority in the first instance from the crown; so, on the other, whatever judicial authority the king originally possessed, it was possessed as in a reservoir, and has since all passed out of him into the appointed channels of his courts.

Direct interference on the part of the crown with the integrity of the judges was unfortunately not peculiar to the Stuarts; but it ended with them. It was carried by them also to such extravagant and unheard of lengths, as to throw all previous outrages of this description into the shade. The ignominy of the imputation has rested therefore principally on their name. Elizabeth had the sense to respect the honour of the interpreters of her laws; so that Coke felt what he called the taking of auricular confessions by James to be a novelty and a disgrace. The course, however, of the whole judicial history of England teaches a great lesson: the extreme difficulty of maintaining freedom with dependent judges. The struggle began at Nottingham, with the treasonable surrender of the infant constitution of their country by Tresilian and Belknap, in their discretionary expositions of law to Richard II. The impunity of intervening centuries tempted the colleagues of Finch and Crawley to believe that, supported by a sovereign at least as arbitrary, they might in their day set parliament at defiance. Although their virtue often failed, yet, in the main, the judges of the supreme courts of Westminster did their duty beyond what could have been expected. Fortunately for their characters, special commissions, composed chiefly of courtiers, were issued on most occasions of jealousy and alarm. In consequence, they seem to have kept their ground in the confidence of the public much better than the subordinate magistrates, who were subject, but in a less degree, to the same influence. These latter never gave much satisfaction. The ancient conservators of the peace, instead of continuing to be elected by the freeholders, were turned, in the first year of Edward III. into nominees of the crown. The necessity of suppressing the malefactors, who appear in those days to have been at times encouraged by members of the nobility, could not prevent the justices so appointed, on the extension of their jurisdiction, from becoming speedily unpopular. A petition from the House of Commons, in the 11th Richard II., declares that "every freeman in the land would be in bondage to these justices." Even in the retrograde years between Henry VI. and VIII., the difference between the independent tribunal of a jury, and that of perpetual officers connected with the executive, was well established. The right that criminal proceedings should follow the course of indictment and of the common law, is repeatedly and earnestly urged. Juries had so far begun to do their duty, that the fiscal purposes of Henry VII. could only be carried into effect by enabling these creatures of his power, removeable at his pleasure, to try all offences except treason and felony by themselves. The restoration of a jury to its pristine rights was one of the measures by which Henry VIII. won, on his accession, the popularity which he afterwards so cruelly abused. This affectation of a return to the old constitutional character of the English courts of justice, was soon overthrown by terrible innovations, like the creation of the president and council of the north, and of the Welsh marches. The worst part of these novelties consisted in their in reality placing the judicial and executive authority in the same hands. What could the subject expect from a tribunal of which Wentworth was the president? Mr Hallam says that these and other irregular tribunals, when abolished by 16 Charles I., had usurped so extensive a cognizance as to deprive one third of England of the privileges of the common law. It was nevertheless reserved for the high churchmen of Charles II. in the year 1664, to return to the charge. Legislating against what they unjustly called seditious conventicles, they ventured to arm a single justice (it is necessary to remember only what were the dependent justices of those days) with the power of inflicting seven years transportation on a third conviction of the offence of worshipping God contrary to act of parliament.

The objection applies still more strongly to the original authority of the sheriff. The shrievalty was generally sold by the Norman kings, and was an office of great emolument, and still greater influence. The coroner, with his limited inquest of criminal police, was left to popular election. But the sheriff, from the conquest downwards, except during the sixteen years which intervened from the 28th Edward I. to the 9th Edward II., was nothing but the annually nominated servant of the crown. Great judicial authority was intertwined with his civil superintendence over his county; the more so, because the law has never sufficiently distinguished between acts which are judicial, and acts which are ministerial only. Although in the hundred and the county, as well as in the baronial court (not being courts of record), the freeholders were the real judges, both of law and of fact, the sheriff's authority was the subject of great alarm. The principal sources of this jurisdiction were by degrees turned into other channels. Criminal pleas were taken from him entirely as far back as Magna Charta. The complaint upon which that clause was founded had only sought that he should be restrained from hearing them except when assisted by the coroner. The confidence felt in the popular presence of that officer for decompounding and breaking up this dangerous identity of powers, appears by several other writs in Rymer. The justices-in-eyre, not being the same always as the judges of Westminster, were probably often but partial improvements on the local administration of the sheriff. Their circuits, however, facilitated the transfer of most of the civil as well as the whole criminal business into a more strictly and purely judicial court. The civil cases still cognizable in the county court, in which the sheriff is both presiding officer and executioner of justice, are the inconsiderable and almost obsolete remains of former usage.

From this brief review, it appears that formerly the judicial power was often placed in the same hands with the legislative and the executive. This probably never took place without the people suffering severely from it. The small territorial jurisdictions, civil or criminal, must have been the worst of all. The existence of other checks at present, and the vigilant rapidity with which public opinion keeps hovering over and bearing down upon all official misconduct, may blind us as to the importance of the principle itself. A hazard, of which the only actual mischief is in the precedent, may seem not too much to incur for the convenience of this or that exception. At the same time, no nation is wise which in such a case presumes too far upon its security. A judge, when member of the legislature or of the cabinet, is in a position which ought to create, both with himself and with the people, a degree of watchfulness, not to say jealousy, far beyond the case of other men. It is to be remarked, that the greatest of all exceptions which occurs in this respect in English practice, that of the Lord Chancellor, occurs in the very instance where the existence of the judge depends on the casualties of the ministry of which he is a leading member. An examination of the judicial removals during the Stuarts shows the extent to which the hopes and fears of the bench were constantly played with. It was a system, and not an accident. Nothing short of the 13th William III. could have put it down. That statute altered the patents of the common law judges, from patents during the king's pleasure, to patents during their own good behaviour. The little that was left to be done, was done at the accession of George III. This last amendment consisted in excepting their commissions from the fate of all other crown appointments, that of being vacated on its demise. It was a very prudent waiver of the little remnant of arbitrary power which, strange to say, had in the interval been misused. But the waiver could of necessity be made by any actual sovereign, solely at the expense of his successor. If a stop had been put to the analogous suspicions connected with the promotions of judges and the translations of bishops, it would have obviated an evil of more frequent recurrence. On considering the elements of the character and of the happiness of the nation, the English people are perhaps not more indebted to their participation in legislation by means of the House of Commons, than to their share in the administration of justice in the capacity of jurors. Not only has the executive been kept at bay by their interposition, for the legal verification of the fact at issue, but the legislature has received more than one useful warning from their collateral influence on the law itself. For both these purposes it was indispensable that intimidation should be removed from a juror as thoroughly as corruption; and that offences imputed to him in the discharge of his duty should be investigated and punished as cautiously, as reverently, and before as impartial, if not as solemn a tribunal, as similar offences imputed to a judge. The day when, in Bushell's case, the court relinquished the pretension of fining or imprisoning a jury for its verdict, ought to be as memorable as any in the annals of the victories of justice. It heralded in, and was in no degree less important than, the day which made it impossible that any successor of Pemberton (for even the chief-justice who tried Russell had paid too much respect to freedom) should be arbitrarily displaced. In this point of view the dissatisfaction expressed by Jefferson with the corresponding rule in the constitution of the United States, that the judges are irremoveable, except by a resolution of two thirds of congress, is very surprising. The exception would seem amply sufficient to secure the legislature the necessary discretionary control. Considering the position occupied by the ordinary courts of justice in the United States and in England, it is impossible that they can make any serious encroachment on the other departments of the state, without a degree of negligence or connivance on the part of the legislature utterly inconceivable. The cry against judge-made law, on the ground of its being an unwarranted encroachment, appears also, to the extent to which the common law courts have carried their incidental legislation, to be quite unfounded; and most of all in England, where the common-law judges are much more justly liable to the inconsistent accusation of standing too stoutly upon the letter and strictness of the law, and of having brought on the necessity of an equitable jurisdiction and of irregular tribunals, from their narrow adherence to precedents and forms. They are not answerable for the main defects of the English system, whether in the body of the law itself, in the centralization of the metropolitan courts, or in the inadequacy of the local jurisdictions.

Executive power.

A government, where in point of form the legislative and judicial authority appears to emanate from the crown, is certain to have placed its executive power solely in the king. Long after the two former authorities have succeeded in gradually emancipating themselves from every thing but the antiquarian recollection of their original subordination, the latter arrangement will in all probability retain its pristine vigour. This is the consequence of the substantial advantages which belong to a single and permanent executive. Such, at least, has been the course pursued in England. The founders of the republic of the United States, from their near observations upon the French Directory, and from their personal experience of the disunion of executive committees during the war of independence, admitted the propriety of placing the necessary powers of the general administration in the hands of a single individual. The name, whether king or president, is hardly worth discussing. The great questions are, the mode by which this supreme magistrate shall be appointed, and the powers with which he shall be invested. In comparing with this view the English and the American systems, the principal difference between them is in the mode by which the executive is appointed, and not in the amount or nature of its powers. In their jealousy of the concentrating effect of power, the Americans have subjected all the members of congress, the senate as well as the house of representatives, and the office of president equally with the senate, to the principle of rotation; only differing in the degree of rapidity with which the elective wheel in the several cases performs its circle. By this specific the evil tendencies of political power are supposed to be reduced within manageable limits. Impartial spectators, on comparing the risks of hereditary descent as experienced in England, with the risks already manifested in the quadriennial presidential elections of America, may perhaps be disposed to decide in favour of an hereditary parliamentary title, with reference to the actual passions and prospects of society. A four years' lease of the president's chair may be too exciting a prize to be safely left to popular competition. Besides, the very character and abilities most likely to be admired, are those on which the temptations of such an elevation must act with the greatest force. It is one of the advantages of the English system, that whilst the doctrine of descent greatly limits the probability of dangerous talents in a sovereign, the mechanism of the constitution is so well arranged and understood as to do its work without them. The powers vested in the royal executive are not extreme; for they are nearly the same as those which it has been found necessary to maintain in the United States, notwithstanding all the advantages of a new country.

Under an ancient but progressive government, the executive authorities of the chief magistrate, like all the other authorities of the state, must be capable of being considered in three different points of view. These are, the historical, the actual, and the philosophical. Its constitutional history will vary, both in the facts which it exemplifies, and in the reasoning by which it is explained, at different periods. The correct legal description of it at any given moment, for instance the present, can represent at most only the law and practice of the age. The philosophical conclusion, how far it ought to extend in reason, may be, and probably will be, only obscurely signified in either of those inquiries. Mr Allen, in his inquiry into the rise and growth of the royal prerogative in England, and Mr Hallam, in different parts of his constitutional history, have left little to be added upon the first division. Mr Bentham, in his treatise upon legislation, has generalized upon the last. The legal exposition of the second is all that Blackstone properly undertook. Nothing certainly can be more absurd than the language which he has copied, in order to express the paradoxical fictions of the supposed attributes of sovereignty, perfection and perpetuity. The parliament which consented to describe the forfeiture of the crown by James II., under the euphonism of an abdication, proceeded in the selection of the word on many precedents. Their ancestors, at every compromise with royalty, had demonstrated much indifference to words, provided that the end and consummation were substantially achieved. In English constitutional law, an unlimited and almost oriental deification of expression is found alongside of rights strictly limited and specifically defined. The Plantagenets, however, were much more cautious than the Tudors in bringing this inconsistency to the test of a collision. Unluckily for the Stuarts, they were mystified by the welcome homage of servile civilians and meddling churchmen. By forcing on the solution of the problem, they learned too late, that from the fact of the prerogative being incorporated with the law, whatever was not found there could not possibly be within it. Even Locke's definition of prerogative, which Blackstone has thought fit to praise, is too liberal, not only for the rights of reason, but for the rule of law. "The discretionary power of acting for the public good" does not extend to all cases "where the positive laws are silent;" but to such points only as the constitution has expressly reserved for this discretion. Otherwise we come to the intermediate inherent power on which James I., in his Flowers of Grace, claimed for royal proclamations the force of temporary laws. The proper course on such extraordinary occasions is for ministers to act on their responsibility, and trust to parliament for an indemnity. The Stuarts were doomed to make the additional discovery that, among prerogatives strictly legal, there were some, both prerogatives of authority and prerogatives of revenue, which, being false in principle and mischievous in effect, the public had become sufficiently intelligent and powerful to recall. Our early kings, in the insidious reservations (*salvo jure coronæ nostræ*) by which they narrowed many of their most popular concessions, had succeeded in a great measure in rendering that part of the constitution unimproveable and fixed. This was the course, before notions of an abstract *jus regium* by consent of nations, or the doctrine of a native immortality in the prerogative, which acts of parliament even could not reach, had been yet imported into courts of law. A struggle which could only be kept up by these new and desperate assertions, was evidently near its close. These novelties were in part the penalties of the Reformation, at least as applied to England. Henry VIII. obtained for the crown a new prerogative on that occasion. It was a more dangerous one than perhaps all before it, in consequence of the greatness of the subject which it concerned. The act of supremacy was the corner stone of the high commission court. Mr Hallam truly observes, that "the real aim of the clergy, in enormously enhancing the pretensions of the crown, was to gain its sanction for their own." They played into each other's hands. If, as Mr Hallam affirms, the nation might be considered, up to 1640, as having been, "in regard to spiritual dominion, a great loser by the Reformation," it would have lost every thing in regard to the crown, had civil liberty depended on the loyal sophistries of the church. The apparent strength of the executive on the breaking out of the civil wars, presented so formidable an aspect, as to deceive even Strafford not only into a desertion of the cause of the people, but into the adoption of the language and sentiments of Laud. From the example of former times, and from the external superiority which necessarily surrounds the throne, he egregiously miscalculated the means of the two parties who were then about to decide this battle by an appeal to arms. It is scarcely less surprising, after its result, to find political judges like Jefferies so intoxicated by the saturnalia of the Restoration, as to continue to hazard these and similar insane *dicta*, down to the very eve of the Revolution. On that event the nation carried the principle of the exclusion bill by acclamation. The exclusion bill was looked upon, from the time that it was first mooted, as the extreme case. It was among the principal argumentative advantages of the Revolution, that it put an end to all discussions founded upon the supposition of inviolable prerogatives, then and for ever.

It is perhaps not too much to say that the *direct* prerogatives, in respect of authority, which were objectionable, are all either abolished, or, in case the law of England allowed of desuetude, are obsolete. Some few *incidental* ones remain, which appear to be in the course of removal; since recent legislation has happily shown a desire to look towards a reformation of the law. It is unfortunate that the direct prerogative, which is on the face of it the most revolting, nevertheless, from its having so long principally supplied the king's service with seamen, demands, in the immediate modification of it, considerable caution. Marine impressment, it must be remembered, came in, however, upon no supposed necessity of this nature. It is the remnant only of a doctrine and a practice which at one time included soldiers, and many classes of civilians. Like most other prerogatives, it was abused under Charles I. for the purpose of extortion. Several of the common people who refused loans are said to have been pressed into the navy. There has fortunately been such little demand for prerogative learning since the great argument of ship-money, that the judgment of Sir M. Foster in Broadfoot's case, in the year 1743, in support of the legality of impressment, was wanted to recall the attention of English lawyers to the several conditions which the law requires as evidence of a subsisting prerogative. The debates on the alien act revived these discussions for a season. The lawyer and the statesman look at questions of this kind from different points of view. The first regards what is; the second, what ought to be. For whether the particular powers are wanted, and where they should be placed, are further questions. In case these questions are settled in the affirmative, it is unwise, by division, rotation, or a multiplicity of checks, to reduce their efficiency below a certain point. Society loses more than it gains by such expedients, as often as necessary powers are thus incapacitated for the due performance of their functions. This was frequently attempted in ancient times. On the other hand, governments cannot be too cautious against the abuses which constitute the provocations to such restraints. Unjust interpositions of the *nolle prosequi*, and of pardon by the crown, gave popularity to the appeal of murder. Lord Holt, looking back rather than around him, called the anomaly "a noble remedy." Several petitions were vehemently urged by the commons of former days against the generous prerogative of mercy. The degradation by James I. of the prerogative of honours, by bartering them, for the first time in English history, for money, and the subjecting the peerage by Queen Anne to the personal ambition of a minister, have the same tendency. They bring the prerogative itself, as well as the subjects of it, into disrepute. The prerogative of making peace and war was tarnished by the base negotiations of Charles II. It was damaged later still, when Chatham himself was not able to withstand the electoral prejudices of his sovereign in behalf of a campaign in Germany. The observation may be extended through every department of administration. It applies especially to the formation and the government of so jealous and delicate an engine as that of a standing army. The moderation which the executive had displayed in the exercise of more qualified powers, could alone have introduced into and kept in the mutiny act the clause by which courts-martial are enabled to punish mutiny and desertion with death. It was inserted for the first time in 1718; and it was only carried at the time by small majorities. Of the impolicy of creating an atom of waste power there can be no dispute. But if the power is really wanted, they are sorry horsemen who are obliged to keep the strength and courage of their horse permanently below his work, as their only means of riding him. On the supposition that the powers are fitting powers for the executive magistrate to possess, the appropriate remedy is to apply ministerial responsibility to such cases, and to take care that the responsibility shall be a reality and not a name. The healthiness and *vis medicatrix* of the general system must do the rest.

The prerogatives of revenue depend on a different class of considerations. The financial purchase of tenure by chivalry from Charles II. and the subsequent arrangements entered into on granting successive civil lists, have not gone so far towards completely sweeping out the holes and corners of the exchequer as might have been wished. The last fibres of the barbarous fiscal pretensions which flourished there in former days have still to be rooted up. The national revenue, properly considered, consists of the portion of his property which each subject contributes to the state, in order to secure the remainder. That being the just principle, its demands should be limited in amount to what is necessary for the proposed object, instead of setting a fiscal net to catch an irregular and indefinite number of certain matters. Further, by an accurate calculation and repartition, the necessary taxation ought to be equally borne, in respect of their means, by all the king's subjects, instead of falling upon particular individuals on the happening of particular contingencies. In its original state most of the ordinary or prerogative revenue raised the least possible sum with the greatest possible inequality and inconvenience. The greater part of what remains is only remarkable for its picturesque absurdity. There is, however, one terrible exception, far too monstrous to be left for mitigation to the humanity of the treasury. Nothing can be worse than the wholesale forfeitures and confiscations which still sweep in the train of our criminal proceedings. In spite of the praises bestowed by Blackstone on Mr Yorke's essay in defence of the law of forfeiture, and although the people owe the 25th Edward III., which has been called the magna charta of treason, almost solely to a squabble between the king and his grantees the barons, for their several portions of the spoil, according as the late owner had been found guilty of treason or of felony, it is impossible that the reason and humanity of a great country can much longer permit cruel iniquity, abandoned by the most civilized part of Europe, to be justified upon antiquarian learning or by metaphysical refinements.

Blackstone's declaration at the commencement of his chapter on prerogative, that the powers which are vested in the crown by the laws, are necessary for the purpose of society, may be thought even now, if their whole detail is minutely examined into, to go something beyond the truth. The exceptions, however, can be in practice of no great consequence. The most obscure member of parliament would have nothing to do at the present day but to attack any indefensible exception, by a motion for its repeal. From the era that a general control over the government passed into the House of Commons, influence has so much superseded force, that questions of pure prerogative have lost much of their importance. According to present usage, any transaction arising out of its exercise, if it is at all interesting or doubtful, must be brought sooner or later before the House of Commons. The difference in the three modes of proceeding, between which alone a minister has to choose, comes to little more than the option at which of its stages the transaction shall be brought there. This will depend on circumstances. It may be a case in which there is no pretence of a prerogative, as on a suspension of the habeas corpus act. Or the principle of a prerogative may be pretended; but it may be suggested that the means for carrying it into effect are defective, as was suggested in the alien act. If there be time to apply to parliament to strengthen the executive, a prudent adviser would recommend, especially wherever a continuous measure is required, of necessity, on the first of these supposed occasions, but on both of them would he equally recommend, that the authority of parliament should be called in. In case a temporary emergency arises, more especially one which will not wait for parliament, as in the instance of the embargo laid by proclamation upon vessels laden with wheat in the scarcity of 1766, every administration is bound to take the responsibility of the measures demanded by the emergency; and parliament is bound to indemnify the authors of them for venturing upon a discretionary rigour beyond the letter of every day's law. The third supposition yet remains to be mentioned. When a minister is confident of the existence of the prerogative, and that the necessity for exercising it has arrived, there can be no occasion that the immediate representative of the executive should advertise for a parliamentary discussion. Let him use the instrument in the manner in which it was left by the constitution to be used. The opposition for the time being have it always in their power (and may be usually trusted for the inclination, as in the late Dutch embargo) to press the question to issue, and obtain the opinion of parliament upon both the point of right and the point of policy. For, on state-questions of this description, the members of a government are as answerable to the community which they serve, for mistakes in policy, as for mistakes in right. The distinctions were only of use before the House of Commons ventured upon the general superintendence which it exerts at present. Blackstone observes, that "the king, in the exertion of lawful prerogative, is and ought to be absolute," subject to the responsibility of ministers. Yet, from the nature of the case, as it is now understood, the king cannot be more or less absolute, nor his ministers more or less responsible, within than without these bounds. An unlawful prerogative may be assumed, a lawful one may be abused. As long as the constitution lasts, the king is in both cases alike personally secure. The unconstitutional adviser is in both cases equally answerable upon impeachment, and to the same degree. The decision against general warrants, when the official practice of three quarters of a century was at last brought into a court of justice, exemplifies the jealousy of the law in its own defence. The truth is, that the most satisfactory account of the mysterious maxim, that the king can do no wrong, since for every act done by him there must be responsibility somewhere, is an innovation which even the Revolution itself did not immediately introduce. The earliest strong assertion of it which Mr Hallam has perceived, is in a speech by the Duke of Argyll in the year 1739. Public opinion must have stopped short indeed, when a Whig, like Burnet, thought ministers were liable for advice given at the council, but not for the resolutions taken there; that is, they were to be liable for their own words, but not for the act, which might be the act of the sovereign himself. Whilst this distinction remained in force, it was possible that the whole question in these cases might turn on the limits of prerogative, and on the fact, whether the necessity of coming to parliament for fresh power could be evaded. This distinction, or something not distinguishable from it, was the shield behind which, strange as it now appears, both Whig and

Tory ministers, Somers as well as Harley, alike retreated, since the Revolution.

Prerogative, as above treated of, regards solely the remnant of those powers and privileges which had been vested in the crown from time immemorial by the common law. What is left is a small portion of a heterogeneous sovereignty, which had been originally wrested from a weak community by mere force, or which pertains to principles and circumstances long since decayed. From a sort of obscure traditional feeling, the word prerogative is more associated in men's minds with the personal will and pleasure of the sovereign, than with his political and strictly legal duties. The thing itself has, however, gradually fallen into the general mass of executive authority. Considered in this point of view, great additions have in later times been made to it. These additions consist of powers derived directly from parliament, and transferred to the supreme magistrate on the simple supposition that they are necessary for the public welfare. The preliminary question, Are they indeed necessary? occurs still more naturally on a demand that new powers should be granted, than on the suggestion that ancient powers might properly be retained. It is only when that point has been made out, that a prudent legislature will enter on the consideration of the precautions by which their abuse may be prevented, whilst their efficiency is maintained. To mention only one or two examples: The patronage of office has its risks in a free government. Yet it must be remembered that Polybius saw, in the influence which the contracts and public works gave to the Roman senate, the necessary link by which its connection with the Roman people was held together. At all events, the disadvantages of the actual extent of ministerial patronage belongs to the greatness of the British empire, and to the nature of its colonial possessions. The most rigid economy can alone reduce it within certain limits. An enormous national debt must still leave the public burdened with the additional evil of a proportionately enormous fiscal law; more equal in its assessment than, but perhaps almost as harassing as, the ruder aids and incidents of feudal jurisprudence. It is made both more costly and more pernicious, from the childish weakness of insisting that the bitter pill, if it must be taken, shall be concealed under the form of indirect taxation. The difference in the powers, as given by the common law and by the riot act, to public officers over unlawful assemblies, is scarcely so great as to be considered a dangerous augmentation to the force of any government. At the same time, whatever it may be, the same authority, or something very like it, may have become necessary for the preservation of the peace, when a vast manufacturing population is collected together on one spot; liable to be thrown out of employment at every moment by the oscillations of trade; accessible, besides, and accustomed almost daily to the most inflammatory appeals. This is the case also with regard to the extension of a regular police, and to the employment of the military in subordination to a civil magistrate. The change, however, which would most surprise Whitelocke and the patriotic parliamentmen who argued the militia question under Charles I., would be the mutiny act and the army list of the present day. They would think that the king might well consent to the concession of coming to parliament for its sanction, as his portion of the compromise. The balance of power in Europe was the only cause at first assigned in justification of a standing army; and it is still the burden of the mutiny act preamble. Our immense provincial dependencies have also to answer for it in part. However, another and a domestic necessity must have been silently making prodigious way, when so cautious a statesman as the late Lord Liverpool defended in parliament the numerical increase of the army, not by a reference to the state of Europe or the colonies, but by a comparison between the amount of the population now and in former times. It would be impossible to govern with so slight a pressure as society is at present used to, without a strong executive. It is fortunate, therefore, that, from the systematic regularity which prosperous civilization has favoured, the actual powers of the executive government have become more consolidated, and their operation more uniform. The effect of the whole is, that in Mr Hallam's opinion at the time of writing his invaluable work on the constitutional history of England, the English executive, "though shorn of its lustre, has not lost so much of its real efficacy, by the consequences of the Revolution, as is often supposed; at least, that with a regular army to put down insurrection, and an influence sufficient to obtain fresh statutes of restriction, if such should ever be deemed necessary, it is not exposed, in the ordinary course of affairs, to any serious hazard."

On the supposition that this opinion was correct at the recent period when it was delivered, experience alone can determine how far the supposed influence alluded to in it has been affected by the subsequent change in the constituency of the House of Commons. The supposed euthanasia of the English constitution, namely, the establishment of that simple monarchy which Hume and other writers have predicted as its natural fate, has been thrown back to an indefinite distance by parliamentary reform. If any thing like the same good sense and good fortune which have hitherto prevailed in the history of the people and their government shall be continued, there seems little reason why they should be thought to be hurried, by a measure of that principle and extent, within the perils of the opposite extreme.

Neither the principle nor mechanism of the reform bill has so changed the nature of the account. The difference of opinion entertained by different persons on a general comparison of the forces at work in the English constitution, seems of itself positive proof that the variance, whether before or since, has been only in the inclination, but that the constitution is on its balance still. At the same time it must be admitted, that the interest which was strong enough to carry the reform bill, is tolerably secure. It is not difficult to prognosticate what would have been the issue of open resistance to the new political adjustment which has been settled upon its terms. It was impossible, also, from the causes which urged it forward, that the adjustment could have been much longer peaceably delayed. The impoverishment of the crown by the alienation of the royal demesnes; its abandonment of claims and maxims become odious or ridiculous; its political incapacity to act on the House of Commons by the disfranchisement of old or by the creation of new boroughs; the scandal of private nominations, the still greater scandal of corrupt corporators and bribed freemen; the doors of parliament thrown open to the people through the publication of the debates by means of a daily, almost an hourly press; the increase of dissenters, displacing the monopoly of the clergy; a liberty, nay license, of discussion, popularising crude analogies to a new and kindred democracy in the United States, and reaching over every question and up to every individual in the land; public opinion circulating from one end of the kingdom to the other, and brought concentrated with electrical rapidity at any moment to any point; the rights of conscience, of free opinion, and of political equality, so proudly recognised that they overcame at last even all the recollections arrayed against the Roman Catholic persecution of Protestant reformers; the universal responsibility of ministers for every act of government now as universally acknowledged; the rise of immense towns, swarming with active artisans easily excited and easily combining; the constant accumulation of numbers, competence, and intelligence in the great and powerful body of the middling classes; the disappearance of the last relics of feudal castes and prejudices; the swamping of the ancient historical nobility by a modern aristocracy of wealth, favouritism, and corruption; the final breaking up even of the court and country party, whilst in their stead had risen up and found themselves face to face, those two parties which must always exist in open commonwealths—on one hand, the honest and also the servile partisans of power—on the other, the seditious and also the constitutional friends of the people;—these are but a part of the alterations which had changed not only the face but the core of England. A new soil, so to speak, had been turned up. A revolution in society had outstripped the Revolution of 1688. The rights of Englishmen, as Blackstone calls them (but what are in truth the rights of man, wherever man is civilized enough to understand and to preserve them) had grown into fuller consistency and bulk. The national system, now in its manhood, made, as it were, more blood, and required that the arteries should be enlarged which were to carry it to the heart.

A political student, after looking at the points to which all governments should strive, at the imaginary commonwealths of theory, and at the degree of approximation which, from amongst their thousand experiments, mankind appears to have ever realized, may think that there is good reason to be content both with the end and with the means which the English constitution recognises and secures. He will perceive that English liberty was long heavily mortgaged, but that the mortgage was never foreclosed. Its standard-bearers were sometimes down, but the pennon itself was always flying. Nations who regard England as a model, whether to be copied or to be surpassed, should remember that no nation can hope to buy a suitable constitution ready made. The end ought to be one all the world over, namely, the happiness of the people. But the condition of the people may be so different, as necessarily to demand the greatest difference in the means. The quantities with which moral and political problems have to deal, so far from being fixed, are in constant fluctuation; and the truths which they have to establish can never be tried by taking extreme cases. An assimilation and correspondence between that which acts and that which is acted upon, are conditions grounded on the nature of the human mind. In no case is strict attention to them more indispensable than in the relation between a people and its institutions. The best security for this is gradual adaptation. The Americans take English experience and English character into new circumstances, with the woods to back them. They may ride with a looser rein, and may try bolder tricks in legislation, than, in an old, densely-peopled, and overwrought community, any person, at least any reasonable person, acquainted with human nature and the difficulties of the case, could venture to recommend. They will not undervalue the necessity of such compromises with the nature of things and of events; since, in truth, no country ever made a greater sacrifice to the predominance of circumstances over principles than America has made, and is still making, over half her empire, in the most fatal of all exceptions. It is a worse one than the barbarism of the barbarous age of Magna Charta; an exception limited not even by the test of freedom, but that of the colour of the skin. It may be doubted whether the English experiment would not have failed, as the same experiment failed elsewhere, if its authors had rushed in the first instance to the point where their posterity at present stand. Light things may hurry forward, but the elephant must make sure of every step he takes.

A free government must be complicated in its parts. The checks introduced by circumstances, habits, and opinions, and which have been subjected to gradual amendments, remain a hundred times more effectual than any mere appeal to reason, which is all indeed that a totally new system has to make. The latter, however theoretically superior, must trust to its argumentative merits for its hold on the minds and affections of mankind. Montaigne expresses great contempt for long philosophical discussions concerning the comparative advantages of different forms of government. When he refers not only in opinion, but in reality, to usage as the sole criterion in every case, he is guilty of a gross exaggeration. This however ought not to prevent due respect being paid to the truth on which the very exaggeration is grounded. The whole history of England is the narrative of a long preparatory schooling to fit its people for their actual institutions. Institutions certainly are faulty which cannot stand the more summary test of Pope, when he disposes of these questions by a single line, "whate'er is best administered is best." For this in sensible prose must be understood to mean that the government is best which contains the best provisions for securing a good administration of all public affairs which depend on the relation of the governors and the governed. This security, it will appear by the description which has been given, it is the great object of the English constitution to establish by the proper formation and distribution of the legislative, judicial, and executive power.

II.—LAWS.

The civil law approached to the character of a universal language. The breaking it into fragments on the fall of the Roman empire, and the substitution in its stead of the coarse and mixed materials of the barbarian and feudal codes, had the effect of the confusion of tongues. Each code was nothing more than a partial dialect. Whilst the rest of Europe fell back more or less under the legal dominion of its ancient master, England alone stood out. It was impossible, however, that it could altogether resist an influence so universal; and it is probable that a greater impression was incidentally received than contemporaries were aware of, or than antiquarians have since been at the trouble to retrace. Mr Hallam observes that a good work, pointing out the extent to which the Roman law affected Bracton and his successors, is a desideratum in our legal literature. Nobody has yet felt a sufficient interest in, or been sufficiently conversant with, both systems to supply it. The distance to which England was thrown from the common orbit of classical jurisprudence, appears to have been even something more than the difference which separated the northern and southern divisions of France, where the one was subject to a customary, and the other to the Roman law.

English civilians and foreign scholars always treated the vernacular common law with the greatest possible contempt. John of Salisbury, in the reign of Henry II. calls it *aucupatio verborum*. Whitgift derides the learning which is learning nowhere but in England. Erasmus must have seen it to great advantage in the person of Sir Thomas More; nevertheless he mentions its professors in terms scarcely more respectful than the scurrilities of the college-play of Ignoramus, got up in its ridicule for the entertainment of James I. Evelyn is content so that he escaped from it with no harder word than "that impolished study." The provocation given by Law-Latin and

Government and Laws.

Law-French has since been got rid of; that of tenures and their commentators still remains. Any insular jurisprudence, growing up during the middle ages, must have certainly suffered in its philosophy and its symmetry by excluding the written wisdom of the Pandects. By way of compensation, it is suggested that the alienation was of great advantage to English freedom. Whatever was gained in this direction is probably to be attributed more to the class to which the professors of the two systems respectively belonged, than to the supposed exemption of black-letter precedents from the arbitrary spirit of the imperial constitutions. The Inns of Court were long the principal seminaries in which the gentry of England completed their education; whilst, in the universities, the foundations for the study of civil law rivalled those for the study of divinity. The civilians and canonists, cousins-german by descent, thus became twin-brothers in feeling. In fact, civilians were formerly almost always churchmen. The difference of pedigree between them and the common lawyers was visible down to the time of Laud. The civil law, in any comprehensive sense of it, may be said to be extinct in England. To the degree, however, in which it exists, the English constitution is likely to find as warm supporters at present in Doctors Commons as in Westminster Hall.

The first point, on inquiring into the laws of a country, is to ascertain where the power of making them is lodged. It is very desirable that, as far as possible, the power should rest exclusively with the distinct and supreme authority of a recognised legislature. In this manner, laws adequately and publicly discussed will receive perhaps as general and as efficient a promulgation as the subject admits of. Certainly no better security can be devised against the possibility of constructive and *ex post facto* liabilities, than the practice of open debates, and the rule that legislative measures shall be strictly prospective. The connection between legislation and legislature is the doctrine of the English law. It can nowhere be expressed more strongly. But the history of what is called the common law shows the difficulty of acting upon it throughout. Popular customs will have already taken root before a steady government is formed, or, at least, before it is so far universally established, as to take under its cognizance the whole field of legislation. With regard, therefore, to this class of self-sown customs, the best thing probably that the legislature can do, when it becomes adult, is to acquiesce in them. Certain divisions of the law, and those not the least intricate and important, will from time to time be elaborately commented upon in text-books. Particular rules will also be adopted by the profession; and these soon become the grounds on which properties and expectations rest. For instance, "the practice of conveyancers" easily goes the length of making by necessity the law in that department. Much more is this the case with the opinions and the practice of the regular tribunals. For this purpose it is by no means necessary that the statute-book should contain an intimation corresponding to the threat of the *Code Napoleon*. "Le juge qui refusera de juger sous prétexte du silence, de l'obscurité, ou de l'insuffisance de la loi, pourra être poursuivi comme coupable de déni de justice." Direct legislation must be infinitely more active, and must complete its work in a far more workmanlike way, than the parliaments of the Plantagenets, and even than the parliaments of to-day, not to leave vast chasms for judicial construction to fill up. The English law at different periods has been indebted to all these collateral sources in different degrees for accessions to its wealth. Nobody can now determine how far Alfred and our other supposed lawgivers collected or composed the documents transmitted in their names. It is not the less unreasonable to assume on that account, with Chief-Justice Wilmot and others, that the "common law is nothing else but statutes worn out by time." Madox has observed that the laws of the Anglo-Saxon kings are as different from the writings of Glanville as the laws of two different nations. Some of the points are brought out in contrast in the second volume of Mr Hallam's *Middle Ages*, p. 466. Yet, if we are driven to any particular date for the origin of the present common law, it must be a moment not much anterior to the age of Glanville. He wrote as early as the year 1180; and the laws called by the name of Henry I., which are in their spirit thoroughly Anglo-Saxon, must, by their mention of Gratian's decree, be as late as the very end of the reign of Stephen. Mr Hallam makes a very judicious suggestion. He supposes that these laws, like the water ordeal for the common people, contain the ancient usages of inferior jurisdictions, whilst the treatise of Glanville, he conjectures, comprehends only the rules of the Norman lawyers, by which, through the influence of the circuits, and by other means, the former were gradually superseded. The unwritten usages were become completely fixed by the time of Bracton's compilation, towards the end of the reign of Henry III. There are no grounds whatever for conjecturing that these fluctuations were preceded or ratified by any direct legislative notice.

At a later period, namely, in the year 1322, it was explicitly enacted that all matters to be established for the estate and welfare of the realm should be treated in parliament. After so solemn and public a declaration, it might much more plausibly have been supposed that every subsequent alteration, whether in the civil or in the criminal law, would be accompanied by a parliamentary sanction in evidence of its title. What a change, however, took place both in one and the other; yet no "statutes worn out by time" can here be pretended. It is indeed remarkable that the statutory changes long bear but a small proportion to those which were obtained from other quarters. Although usage after this period can have crept in only now and then imperceptibly, undoubtedly the sages of the law kept insinuating their opinions, even extrajudicially, from time to time into the system. But by far the greater part of the innovations, real and apparent, were derived through the means of judicial decisions preserved in reported cases, and argued out by help of what has been quaintly called the "logical deduceableness" of the principles of the common law. The grounds of every judgment were set out on the record till the reign of Edward III.; afterwards they were taken down by certain grave and sad men in the year-books; and latterly, they have been left to reporters of a less accredited description. These precedents constitute an immense repertory of case law. If regard is paid to the smallness of the basis compared with the vastness of the superstructure, the ordinary course will appear to have been the synthetical formation of general rules out of the application and extension of individual instances. The portion, however, is far from being inconsiderable, in which the judicial classification of particular facts has proceeded according to the *allegata et probata*, under certain established principles. Looking at the history of the science, Burke was justified in saying, in the report of the committee upon the impeachment of Warren Hastings, that "to give judgment privately, is to put an end to reports; to put an end to reports, is to put an end to the law of England." Reports of the leading cases are especially valuable where society and the law are in a state of transition. Without them, the law in such periods soon becomes what Lord Bacon says the law of his time would have become without the reports of Lord Coke, a ship without ballast. The whole equitable law of the court of chancery, now tied up as strictly as the common law itself, has been spun, with but very slight exceptions, out of maxims of conscience and limits upon discretion, laid down judicially at as late a day as that of Lord Nottingham and the Restoration. That part of the English system where at present the lucubrations of twenty years are more wanted than in any other, was still in its infancy little more than a hundred years ago. Sir Mathew Hale said, in 1672, "a little law, a good tongue, and a good memory, would fit a man for the chancery." Evelyn, noticing the death of Chief-Justice Treby, in the year 1700, adds, "The chancery requires so little skill in deep law learning, if the practiser can talk eloquently in that court, that probably few care to study the law to any purpose." Lord Nottingham could not have desired a successor more admirably qualified than Lord Eldon, to remove from his court the last traces of this reproach. His ingenuity and erudition, however, only added still further to "the mass of learning which no industry can acquire, nor any intellect digest." Vesey junior, and his voluminous successors, have accelerated the predicted "crisis of a necessary Reformation, when our laws, like those of Rome, must be cast into the crucible. It would be a disgrace to the nineteenth century, if England could not find her Tribonian." (Hallam.) Mr Bentham admits that this legislative crisis will find, in the store-books of our reports, materials of a higher and more authentic character than were ever in the possession of any other country. Although the amendments of the law in the last session of parliament were more extensive than those of any single reign since Edward I., they nevertheless do not affect to have been of a nature to ascertain the existence or non-existence of a present Tribonian amongst our reformers. The extent of the alterations which have been begun or are anticipated, may be understood by the complaint of a member of the profession, who has particular means of information. "I regret to find (says Mr Chitty, in his *Concise View*, 1834) that *students*, whether for the bar, or as special pleaders, or as attornies, have of late nearly suspended all study, upon the supposition that, whilst innovations in the law are so frequent, it would be useless one day to learn what must perhaps the next day be forgotten or effaced."

A wise legislature will establish municipal rights in all cases, when by so doing it increases the sum of human happiness. These rights must be derived from the several sources of human pleasure. They therefore necessarily regard property, person, station, character, or opinions. Rights are public or private. Out of the first arise questions between the governors and the governed; to the second belong the disputes of individuals. The classification of these two descriptions of rights, and the specification of the circumstances which are the occasions upon which they vest, constitute the constitutional and the civil code. But rights are delusive unless protected by adequate guarantees. It is the first object of the remedial law, therefore, to define the circumstances which amount to a legal violation of whatever rights the substantive law has conferred. If the injury is considered to affect the public, its recurrence is sought to be prevented by subjecting the wrong-doer to the penalties of the criminal code provided on behalf of society at large. If the injury is of a private nature, the party injured is entitled to recover damages in the civil court for his own personal satisfaction. The mode by which the appropriate legal remedies for an alleged injury are ascertained, is called the trial. Since every case may involve disputed points of law and fact, it is requisite to make complete arrangements for deciding both. The efficiency of a trial will depend upon the constitution of the several courts, and the rules for regulating their proceedings. The first part of this problem concerns the number and locality of the tribunals, the principle upon which each of them shall be formed (as whether of a single judge or more, and with or without a jury), and lastly, the scale of appellate jurisdictions. The chief considerations relating to the proceedings concern the rules of pleading and of evidence, or the method by which a party is required first to make his statement, and afterwards to prove it. When the trial has established the merits of the case, and fixed the nature of the remedy, nothing remains but that proper means should be provided for carrying the judgment of the court into effect. This can be only done by making the property, and, on just occasion, the person, of the defendant duly available to the requisition of the law.

1. *Constitutional Law.*—This has been treated of in the former section. The shape in which the Roman civil law has come down to us, as recast at Constantinople by the imperial jurists, contains not a syllable which can be referred to the supposed resemblance between the mixed forms of government of ancient Rome and modern England. Excepting a few slight privileges belonging to the peerage as members of a second legislative assembly, English equality recognises no distinction but that of aliens and natives. Our doctrine of the unalienability of birth-allegiance, and our restraints on naturalization, are pushed to an illiberal extreme. But it is a great blessing to have escaped the useless and onerous diversity of castes by which Roman policy was embarrassed, and American freedom is disgraced. England is safe from the interminable questions of political rights and civil condition arising among the *ingenui, liberti, servi;* and under the discrepancies of the various kinds of citizenship and the *Jus Italicum* and *Jus Latinum.* Shades of colour have introduced the risk of even still more dangerous collisions into the United States.

2. *The Relations of Private Life.*—Under the English law these relations were for the most part either settled upon, or have been since gradually brought within, the true principle, namely, that of deriving from the connection the greatest advantage to both parties, which, on a comprehensive view of their interests, the particular relation seems qualified to produce. On legislating upon this subject, our law-makers have not overlooked the painful fact, that there is no occasion where it is more necessary to keep constantly present to the mind the line which separates morals from law. The poor-laws and the factory bill are doubtful exceptions, in which the feelings of society may be suspected of having got the better of its judgment. Otherwise, the law has generally forborne from becoming responsible for those private virtues which no law can possibly secure, and has shrunk from an interference far too powerful not to tend to defeat the end it is desirous of accomplishing. In the service of adults, the contract between master and servant is the only criterion both of their claims and of their liabilities. The maxim that slaves cannot breathe the air of England, has at length comprehended our distant colonies within its blessing. The extension of a haughty local privilege into a national truth is the proudest triumph of the humanity and justice of modern times. The relation of parent and child is placed upon proper grounds. Parental authority is reasonably limited to the degree of power necessary for the adequate performance of the duties which every parent is understood to undertake. The most faulty part of the legal distinction between legitimate and illegitimate children is not in the degree by which the parental obligation towards them is distinguished. The feelings of society must first alter, and the policy of our rules, and the most effectual method of attaining our object, must be carefully reviewed, or very

little practical benefit will follow from a nominal amendment of the letter of the law.

The difference by nature and education between the sexes placed the female sex in the East, in Greece, and in Rome, in a permanent tutelary condition. Their disabilities were doubtless represented, as in the case of minors amongst ourselves, to be in reality privileges of protection. Modern civilization has transferred this state of imbecility from women generally, to women who consent to assume the character and *status* of wives. The marriage contract cannot be regarded as an ordinary partnership. Women are certainly the half of the species much the most interested in the rule, that a contract, more or less resembling the marriage contract as it is actually established, should subsist. The only question which their advocates can raise must be upon its terms. It is admitted that the terms are partial. The question still remains, Can they be improved? Nothing is more imprudent than to volunteer speculative changes in an engagement of this domestic nature, without infinite caution in examining into the capabilities of the case. It is impossible to equalize its effects and condition to the two parties. There is an extreme risk of injuring the female by the very precautions and facilities which it has been proposed to interpose in her favour. The interest which other parties (the children and society) have to keep families together, the first of those concentric circles by which a well-ordered community is formed, introduces a new and paramount consideration. The more the subject is reflected upon, the more will it appear that the English law of husband and wife requires only very incidental modifications. By the late amended marriage act (3 George IV.), the reluctant successors of Lord Hardwicke were compelled to retrace his steps, and to submit, on the marriage of minors, to the compromise of *factum valet, quod fieri non debet.* The debates on that occasion affirmed in the most striking manner the necessity of recognising the least of two evils in this delicate chapter of jurisprudence. No necessity, however, exists at all for making parliament the sole tribunal where a marriage can be dissolved. It is a singular anomaly, that this particular contract should become the subject of individual and *ex post facto* legislation in every case where parliamentary divorces for adultery are allowed to break in upon the ordinary law. Our practice does not leave a doubt that the contract should be legally voidable for adultery. But it is very questionable whether, on transferring this jurisdiction to courts of justice, the interests of society in general, and of females in particular, would be promoted by the admission of any other grounds of divorce whatsoever. Nevertheless Cranmer, in the proposed reformation of the ecclesiastical law at the Reformation, was prepared to give to many of the causes on which a separation takes place at present, the effect of a complete dissolution of the marriage. The rule which, subject to a few exceptions, prevents a husband and wife from giving evidence either for or against each other, seems very unreasonable. The legal consequences of marriage do not depend, as Blackstone states, upon any canonical union of persons, which can be supposed to suspend or merge, during coverture, the legal existence of the wife. These consequences are much better accounted for by the rustic simplicity of ancient times, which regarded the wife as only a servant of a better fashion. It is evident that a family partnership, which, when it has once been formed, can be determined only by death or by criminal conduct of a serious nature, requires a conjugal superiority on one side or the other. In this view the law is censurable rather from the discourtesy of the occasional language of some of its authors, than the substance of its provisions. The superiority is certainly evident enough. There is the spiritual promise at the altar to obey, and the legal solemnity which makes it petty treason to kill her lord and husband. Marital restraint and correction carry the power of domestic discipline, in the case of a wife, a greater length than in that of any other servant, except an apprentice. The principle of considering the wife incapable of committing certain crimes in the presence of her husband, owing to her supposed submission to his orders, is made additionally absurd by the inconsistency with which the supposition is applied. It is time that on one or two of these points the law should be put into harmony with the fact. There might also be a wholesome relaxation of the rule by which a married woman is prevented, under all circumstances except the civil death of her husband, from being sued as a single woman. The landed property of a wife could formerly be alienated only by a fine. It was imperfectly protected against the exercise of undue influence, on the part of a grasping husband, by her separate examination. Her real and also personal estate may be made safe enough at present. As far as property is concerned, the devices of a marriage settlement, and the interposition of trustees, seem to accomplish every thing which can possibly be accomplished by law.

3. *Real Property.*—The lawyers of Greece and Rome had no idea of the necessity of two systems; one for land, and the other for goods. In England the systems are entirely distinct. The civil law of England during a very considerable period seems to have had little else but land to treat of. It characterized land by the expressive denomination of realty; and distinguished it still further by establishing its legal title and qualities on exclusively feudal principles. Hypothesis and research will be equally at a loss to make out any analogy between the Roman Institutes and Littleton's Tenures. The language of Craig would have been unintelligible to Papinian. Where the same word happens to be used, it only deepens the contradiction by the difference in its meaning. Dower, for example, by which the Romans described the property which a woman brought with her on her marriage, signifies, in our modern application of it, the life-interest which, on the death of her husband, the widow acquires to a third of his land. The changes in society gradually made it impossible to retain the strictness and also the peculiarities of feudal learning. The "old books" were already antiquated, and several of their cases seldom came into practice in the time of Sir Mathew Hale. The new reports, such as those of Coke, Plowden, and Dyer, the exact perusal of which he pressed upon his student, are now become "old books" themselves, and are approaching towards a similar fate, partly by statutory repeals, partly from desuetude or ignorance, under a still greater revolution in the law. The wave from the commonwealth which, during the reign of Charles the Second, carried off part of the rubbish of former times, did little in comparison with what has been done in the first session of a reformed parliament. The abolition of fines and recoveries; the amendments in the law of inheritance and dower; the limitation of actions, by which writs and formulas of complicated absurdity, hazard, and expense, are gone for ever; hold out substantial encouragement to expect that the labours of the different law-commissions will in course of time be brought to a satisfactory legislative conclusion. In a practical point of view, the registry bill is by far the most important of their present recommendations. An undertaking of much greater difficulty, but fortunately much less urgent, remains behind. The principles, the reasonings, and the language of the law of real property, will not bear an enlightened examination at the present day. Nothing indeed can be more indefensible in the

nineteenth century than a legal system, of which such a book as Coke upon Littleton is the classic. It is a very imperfect answer to say that the opinion which Lord Mansfield once gave to a West India governor upon the law generally, applies especially to this part of it: "Decide according to your judgment, but give no reasons. Your decision generally will be right: your reasons always will be wrong." A code itself would be only a partial remedy, unless it superseded the necessity of looking back into the volumes which preceded it. Feudal doctrines are too completely woven into them ever to be worked out of their text. During centuries when the legislature either could not or would not act, judge-made law was by far the least of the two evils to which the country was reduced. The judges certainly did their best towards accommodating the law to the altered condition of society, by means of the only instrument in their power. But the course taken led naturally into a labyrinth of fictions and refinements, which it will now require pretty much the same astuteness to unmake, as was originally employed in the making of them. The complaint is not that the law is difficult to be understood. That might be expected. What shocks a reasonable person at the present day, is the finding that so many of its rules, when they come to be understood, are irreconcilable with either common sense or with the usages of the community which they govern.

Thus, in descent, instead of regarding the just expectations of near relations, the law is occupied in tracing the blood of the first purchaser. In forfeiture, instead of balancing the claims of the family on one side, and the claims of injured society on the other, the law can see nobody but the original feudal donor. In questions of the lawfulness of a distress, the difficulties do not turn on the point, whether the goods which have been seized represent under the circumstances the fair and natural security for the benefit which the owner of the goods has derived from the premises where they were found, but whether the landlord, on putting an occupier in possession of the premises, had taken care that the terms of the occupation were so expressed as to be sufficient technically to raise a tenure. Independently of judicial construction, successive innovations have materially broken in upon the feudalism of the common law. This is the case, particularly in the restraints imposed upon entails and remainders, in the free exercise of the testamentary power, and in the frequency of terms of years which are regarded by the lawyers as personalty. The most important of all innovations is, however, the extent to which the doctrine of trusts and uses has brought the principal questions concerning land into a court, where forms and principles in many respects essentially differing from those of the old common law prevail. The intermediate legislation respecting uses, from 50 Edward III. c. 6, to 27 Henry VIII. c. 10, is a characteristic specimen of the English method of creeping on step by step, after the mischief has run, like the dry rot, into the frame of society, instead of taking a comprehensive view of the necessary consequences of the new system, and anticipating the confusion by such a conclusive statute as, after all its previous minute enactments, it was ultimately obliged to pass. It answers in civil to the cautious manner with which in criminal jurisprudence the law of *mayhem* advanced, taking successively the different parts of the human body under its protection, one after another, until at last came a general measure known by the name of Lord Ellenborough's act. Blackstone, writing in 1765, observes that the Chancellors, "by a long series of uniform determinations *for now near a century past, with some assistance from the legislature, have raised a new system of rational jurisprudence*, by which trusts are made to answer all the beneficial ends of uses, without their inconveniences or frauds." Considering the strictness of the doctrinal division between legislative and judicial authority, and the traditional attachment to juries, the national submission to this legal revolution, consummated by the great seal, is a remarkable proof of the impossibility of working the system of the common law in the present state of society. It may be questioned whether any country ever adopted, at so comparatively an advanced stage of civilization, so complete a change; with little notice beyond an occasional murmur in some quarters at what was going forward, and that general ratification on the part of the public in the consent that comes from silence. The nature of a jurisdiction like that of Chancery, must be to enlarge, and not contract, its circle. It is now some time since Mr Butler was of opinion that half the estates in the kingdom were held in trust. But there are further changes than those of form. The very substance of certain titles which make a great figure in the law-books is wearing out. Two species of incorporeal hereditaments, common and tithe, to which an extravagant and superstitious importance was formerly attached, seem shortly destined to disappear; and they will carry with them into oblivion a mass of favoured learning. Common of pasture and of estovers was supposed to be so necessary to the advancement of agriculture, and to the maintenance of tenantry and yeomen, that a case connected with it drew forth from Lord Coke the passionate exclamation, "God forbid that the law should not be so, for otherwise many commons in England would be avoided and lost." Long after the Reformation, a still deeper horror continued to be expressed by Spelman and the clergy, at the sacrilegious spectacle of tithe in lay hands, or of land discharged from the payment of tithe. When the necessity of statutes of limitation has been recognised in all other cases, and when even the crown has submitted to be barred by prescriptions of a reasonable extent, the ecclesiastical rule which sent back the proof of a *modus* to a time beyond legal memory, was no less impolitic than absurd. The tithe owner has to contend at present against passion and prejudice, as well as against reason. A violent re-action has taken place. The discouragement to agricultural improvements, from a surrender of a fixed portion of the gross produce, is a ground of objection in which the public at large are interested. The result is, a demand for a general commutation of tithe, which cannot be much longer delayed.

4. *Personalty.*—It is agreed that Bracton borrowed the chief part of what he has said concerning personal property from the civilians. But the reader of the year-books finds himself at the reign of Henry VI. before goods and chattels have become of sufficient importance to make their way as the grounds of litigation into their records. The laws upon property of this description, and on personal contracts generally, are very much the same all the world over. This is probably to be accounted for, not by the supposition that similar laws must have had some common origin; but because these things are too perishable in their nature, and too much the subject of daily wants and traffic, to admit conveniently, under any circumstances, of any great deviation from a common line. The consequence is, that on this point, beyond some occasional quaint distinctions between what is realty and what is personalty, and a little absurdity concerning things which are merely the subject of base property and *nullius in bonis*, there is very little which can be noticed as peculiar in the English law. Where goods have been lost or stolen, the effect which, according to circumstances, prescription and sale ought to have in discussions between the original and the derivative owner, has been settled upon no discri-

minating principle. The rights belonging to an owner when he is out of possession have been slowly recognised in most countries. Blackstone hastily states, that unless a right of property were to be transferred by the sale even of stolen goods, in market overt, "all commerce between man and man must soon be at an end." He should have recollected that England offers the only exception in civilized Europe to the rule, "*nemo plus juris in alium transferre potest quam quod ipse habet.*" In the new questions which have arisen out of the extended intercourse and complicated interests of recent times, it is fortunate for the legal reputation of the country, that the demand for the development and application of the great principles of commercial and maritime law should have taken place at a time when Lord Mansfield and Lord Stowell presided in their respective courts.

5. *Private Wrongs.*—Every right must have its remedy, otherwise it is a right only in name. Verdicts with a farthing damages are sufficient evidence that the expressions *damnum absque injuriâ*, and *de minimis non curat lex*, are confined in practice within narrow bounds. The forms of actions are, in other words, a list of the cases which the law recognises as civil injuries, and which it accordingly promises to redress in that character. One of the great boasts of the English law is the means which it has taken to render illegal imprisonment almost impossible. This was at last obtained, but with infinite difficulty, under the final guarantee of the habeas corpus act. There is nothing otherwise remarkable in its estimate of the wrongs either to the persons or to the personal property of individuals, or in the general quality of the remedies provided by it. The injuries to real property, and the peculiar remedies applicable in the several cases, partake strongly, at least in shape and in language, of the characteristic subtlety and jargon in which the law of real property itself is framed. There are instances, however, with respect to personal property as well as real, where the strictness of the rules at common law had the effect of a denial of right, and drove the parties into a court which undertook to adjust the remedy to the wants and feelings of society. Chancery would never have obtained a tenth part of its present jurisdiction, but that the common-law judges contented themselves with damages, instead of insisting that a contract should be specifically performed and goods specifically restored; and unless they had obstinately refused, since the introduction of uses, to notice the existence of a trust. The bankrupt law has lately been put upon a footing which appears likely to give, in its text and its administration, as much satisfaction as can be imparted to so untoward a subject. Nor does it follow that tradesmen who complain of the million that is discharged by a penny in the pound, are entitled to lay the blame upon either the policy or the execution of insolvent acts. The only effectual protection, that of more cautious credit, is in their own hands. The Roman system placed the debtor at the mercy of the creditor. The American system, according to Chancellor Kent, throws the creditor at the feet of the debtor. The experience of all countries seems to show, that in legislating upon insolvency, it is impossible to reconcile the claims of humanity and of justice by the positive declarations of a universal rule.

6. *Criminal Law.*—Whenever the circumstances and motive under which a legal right is violated imply an injury to the public, it is reasonable that the remedy should cease to be solely of a private nature. The English law is defective in not endeavouring to combine reparation to the party directly injured, as a subordinate object. But it properly considers the mischief to the public, and the remedy for the public, as the paramount concern of criminal justice. The comparative alarm spread throughout society by different offences is the test of their several degrees of responsibility; nor is society entitled to take a criminal cognizance of them at all, save with the single aim of preventing their recurrence. The original point in this respect, from which the common law started, and the mode in which its circle widened, were too coarse and vague to admit of much discretion in the selection of the principle adopted, or of any very uniform correctness in its application. Civilization has tended gradually to exclude from the purview of human punishment the spiritual doctrine of expiation and the savage instinct of resentment. Proceedings *pro salute animæ* are left to the ecclesiastical courts; and the abolition, by 59 George III. c. 46, of appeals at the suit of the party in all offences, has removed from criminal proceedings the last symptom of private vengeance. Up to a very recent period felony was heaped upon felony as a matter of course, whenever a new or temporary provocation happened to arise. No wonder, where it was impossible that due attention could have been paid to the nature even of the specific evil and the proposed remedy, that the just proportion between the new offences and the great body of the criminal law should have also been neglected. In fact, they often seem to have taken their place by chance upon the penal scale. During the last few years the consolidation of great part of the criminal statute-law has been performed in a very workmanlike manner. The repeal of a multitude of obscure and almost conflicting enactments has been of great service to the public, and still more to practitioners. It has simplified the labours of future reformers. But a comprehensive view, a consistent direction, and a rational arrangement of the whole subject, is a task reserved for the commission now engaged upon it. The interests of society, as protected by the criminal law, are technically called the king's peace; and all offences against these interests are prosecuted in the king's name. But it is singular that, nevertheless, the burden and the management of criminal prosecutions, and, in popular language, the name even of prosecutor, should, contrary to the practice of many countries, be thrown upon the party injured. The principal legal consequence which has followed from taking the prosecution formally into the hands of the state is, that society obtains the evidence of the party injured, who would otherwise be excluded as being a party to the suit. The original object of using the king's name in this formal manner was probably to entitle the king, as a matter of course, to the penalties and compensations. A barbarous and fiscal rapacity was thus tempted to scatter wholesale forfeiture with indiscriminate profusion over the field of crime. The 25th Edward III., called the magna charta of treason, had no nobler origin than a contest between the king and the barons, which of the two should appropriate the confiscations upon conviction. They belonged to one or the other, according as the offence was treason or ordinary felony. It may easily be understood, therefore, what little principle exists in the rude classification of offences into felonies and misdemeanors, distinguished only by the nature of the punishment; the one being subjected to general forfeiture, and the other to special fine. Under these circumstances, a strict revision of the entire department of the criminal law, keeping steadily in view the one principle of the good of society, must bring to light anomalies and divergencies which it will be no less desirable than practicable to remove. This is likely to be the case much more in some questions than in others. For instance, the purely religious sentiment was formerly mixed up with the only consideration which can justify human laws in inquiring into offences against God; and it still partially remains so. Judicial perjury is punishable simply

under the general description of being the violation of an oath. If the religious obligation is alone regarded, it may be contended with some plausibility that the breach and the offence must in all cases be the same. But if the danger to society be the point in question, it is clear that the danger must be materially affected by the nature of the case in which the perjury takes place. In some instances zeal without knowledge has been induced to pass the line by which morals ought to be always kept separate from law. The political economy of modern days has overturned many of the most sacred rules of policy and trade invented by the common-law wisdom of our ancestors. It is in vain that the corresponding statutes have been repealed, whilst narrow-minded judges feel a pride in proclaiming that unitarianism, forestalling, and engrossing, are still indictable misdemeanors. The same reasoning which annulled the statutory policy of the intermediate generations, ought to avail for abrogating equivalent absurdities, supposed to have been embodied at an earlier period in the original structure of the common law. In many cases legal definitions, as formerly in larceny, or the specific enumerations contained in an act of parliament, or the purview of a preamble, or the recognised jurisdiction of our actual courts, may be found to fall short of their proper object. It is plain to the understanding of the present day, that the terms of the statutes of treason, which left even Strafford's case to forced constructions, were too monarchical. The decay of the ecclesiastical courts, of the court of honour, and the abolition of the star-chamber, threw loose many offences which have never been examined and arranged on system. It may be doubtful whether seduction and adultery are properly left to a civil remedy only. A doubt however can scarcely be entertained but that the indictable character of words spoken, as distinguished from words written, ought not to be derived solely from their containing a consequent breach of the peace in their tendency to lead to a challenge. There is little foundation in reason for the general rule, which, in slander or libel, admits the truth to be pleaded as a justification always in an action, but never in a prosecution. A careful investigation of the true principles, which, in a compromise of difficulties, may be the best guides on many subjects, will lead to another very important consideration. A great deal of needless, and, what is worse, pernicious pains, appears to have been employed in turning into fixed rules of law what it would be much more satisfactory to the ends of justice to have left as questions of fact. This must happen in all subjects and occasions where the nature and tendency of the act depends on circumstances which it is almost impossible to define beforehand. Supposing, what we see no reason to suppose, that a common jury is incompetent to decide questions of fact of this description, it becomes the duty of society to create a competent tribunal. All offences of opinion are of this nature. But there are numerous others. Notwithstanding the complaint of Sir Thomas More against the judges of his day, that, in order to escape personal responsibility, they threw every thing on the jury, it is evident that, honestly and dishonestly, English judges have brought many points, as legal conclusions of the science, under their own judicial authority, which, as questions of fact, would have fallen, and much more properly belonged, to the province of a jury. National character is involved in the history of the public institutions and policy of a country. England, both at home and abroad, labours under the imputation that the letter, and even the execution, of its criminal law, are severe beyond the example of other states scarcely its equals in general civilization. The difference would appear by comparing a scale of offences and punishments under the English law with a similar table drawn up according to the progressive mitigations which have been attempted by America and France. It need not be feared but that the experience of opposite systems, and a patient discussion of the peculiarities of England, of the nature and circumstances of its population, the distribution of its wealth, and the free character of its legislation, are sufficient securities against vague and theoretical innovation. The result would ascertain what degree of success has attended the humane endeavours of the enlightened statesmen of other countries towards the amendment of their penal codes, and whether any just cause can be assigned why England may not safely venture upon imitating their example. The comparison of the nature of comparative anatomy between the laws of different nations may be very useful. In this instance it would be most satisfactory, were it to terminate, as some confidently insist, in proving that England has already redeemed its right to the distinction which it lost in and after the reign of Henry VII.—*Nulli gentium mitiores placuisse pœnas.* The executions during the reign of Henry VIII. are reckoned by Hollinshed to have averaged two thousand a year. Towards the close of the reign of Elizabeth they averaged annually about four hundred. Notwithstanding the vast increase of our population, and the supposed increase of crime, the criminal return for 1830 gives, on 12,805 convictions, the sentences to death 1397, and actual executions only forty-six. In France the criminal return for the same year (1830) gives, on 4130 convictions, the sentences to death ninety-two, and actual executions thirty-eight.

7. *Courts of Justice.*—The occasions are few and strictly limited, in which the English law allows the party injured, or his immediate relations, to right themselves. A third person cannot justify interfering on behalf of the private interest of even his dearest friend. It is only as a member of society that he can step forward on the public grounds of preserving the public peace. The great singularity of the chapter on preventive justice in the English system, is not, as Blackstone states, that there should be one at all, but that it is so short. There is nothing, however, which a stranger is not privileged in doing, in order to prevent the commission of a felony. In other respects, every one is understood to have transferred the redress of whatever wrongs he may sustain, as well of a private as of a public nature, to the collective justice of the community. Under these circumstances, it is the duty of the community to establish tribunals for a prompt, cheap, and efficient adjudication of the differences which must necessarily occur. The necessity of reconsidering the constitution and distribution of courts, both of original and of appellate jurisdiction, has been at last forced upon the English legislature. Original tribunals may be separated or combined upon four principles: *First*, by the nature of the causes, whether civil, criminal, or ecclesiastical: *Secondly*, By the importance of the proceedings; that is, according to the value of the matter in dispute, or according to the amount of punishment to be inflicted: *Thirdly*, By territorial extent: *Lastly*, By the number and description of the judges, and by the different forms in which justice may be administered in each. The English system admits all these principles.

The supreme courts are classed on the first principle. They were originally founded upon a positive metaphysical division, which went so far as to parcel out particular classes of civil causes to particular courts. Thus all controversies between subject and subject were to be taken into the Common Pleas; all civil questions which might affect the revenue were to be decided in the Exchequer; whilst the King's Bench had the proper cognizance of all trespasses which savoured of a criminal nature, in right of its transcendent authority for the correction of crimes and misdemeanors. By means of rival measures of ludicrous trickery, hardly worthy to be called astuteness, these courts gradually obtained in most civil actions a concurrent jurisdiction. But this jurisdiction unfortunately remained stationary while society advanced. In course of time Chancery took under its charge the vast civil interests with which the common law refused to interfere. Common lawyers were for a time indignant; but they seem, after the first unsuccessful struggle, to have shrunk from entering into competition with the political ascendency of the Chancellors. Consequently, the greater part of this equitable jurisdiction is what no fiction or rule of court has since been ingenious or venturesome enough to reach. Soon after the Norman conquest, it was the policy, perhaps, of the government, but still more of the church, to separate judicially the civil from the ecclesiastical authority. The King's Bench has revenged itself on Doctors' Commons for the encroachments of Chancery, and has always taken jealous care, by its prohibitions, to keep the ecclesiastical courts within their peculiar province. The province is still however considerably larger than present opinion would have made it; for it would be difficult to make out how matrimonial and testamentary questions are properly matters of spiritual concern. The suspicion entertained by Mr Bentham, that the metaphysical classification of courts must have been the result of a scramble between competitors, is not confirmed by our legal history. The scramble began with and brought about the consolidation. Nevertheless, although at first a deliberate arrangement, it seems to have been an injudicious one; and as such, it has been in a great degree abandoned. Every classification of the kind multiplies the chances of clashing jurisdictions. It creates also an additional risk of a failure of justice; since there is a chance the more of a formal error, by mistaking the appropriate tribunal. Each court, having less to do as the business is more minutely subdivided, can supply the judicial demands of a wider area. Thus is superinduced the further disadvantage of extreme centralization. Circuits by the supreme judges at stated periods only partially mitigate a portion of these evils. They have been in use for many ages, and have the very desirable effect of bringing the metropolitan courts nearer to the great majority of the suitors of the kingdom; but it is difficult beforehand to make the calculation of the probable business at the several places of a circuit, with so much accuracy as not to become the occasion of one or other of opposite inconveniences. Causes are often hurried through with indecent haste, or are got rid of by an almost compulsory arbitration; or great vexation and expense are incurred in waiting for a trial, which, after all, is obliged to be put off until the next assizes. The expense of our actual courts is a fatal objection to the exclusive authority which they practically at least enjoy. When it is at once universally admitted that it is cheaper to lose a debt of L.20, rather than to recover it by law, nothing further need be said. In the main examples under the English system for distinguishing courts, either according to the importance of the question, whether civil or criminal, or according to the extent of territory subject to their jurisdiction, both principles are generally combined. This is the case with the baronial, the hundred, and the county courts of the common law. The same combination was observed in the County Court for Middlesex, as settled by the 23d George II. c. 33. It applies also to the Courts of Requests or Conscience, and to the judicial authority given to corporations and to justices of the peace. The subjects which exceed the scale set to these limited jurisdictions, of course lose the benefit of being decided by a local court. By the supposition, a better court is understood to be provided elsewhere. The excluded cases are remitted to it, because either the difficulty of a cause, or the mischief of an erroneous judgment, rises with the amount of the property, and of the penalty which it involves. This is true to a certain degree, but to nothing like the degree necessary to warrant the universality of the rule; and least of all does it justify the distinction at the peremptory point where it is at present taken. Local courts of every description are now scattered up and down the country most irregularly. There are as many as sixty courts of conscience for the recovery of small debts, established among very unequal populations and at uncertain distances. They easily admit of being parcelled out on an improved system. On any reformation of them, the standard of value in civil questions ought to be materially raised. The judicial talent and legal knowledge of the profession, if properly selected, are fully capable of supplying the demand which the alteration would create. The necessity of local courts is a matter of contemporary fact and reason rather than of authority; but if great names are wanted, the plan drawn by Sir Mathew Hale is ample authority for the propositions of Lord Brougham. There can be no doubt but that the confidence of the public would soon be attracted to tribunals which, by their comparative accessibility, would reduce the delay, the vexation, and the expense, within very moderate compass. In this manner the most crying grievance might be removed, and the administration of justice universally facilitated, without giving to our permanent local courts an exclusive original jurisdiction of all cases whatsoever arising within their limit. The circuit system, though open to serious objections, might probably, in a balance of advantages and disadvantages, be the best practical compromise for the remaining difficulties. The periodical visits of the supreme judges, and the presence and example of the powerful metropolitan bar, have doubtless a very wholesome influence in the provinces. They constitute moveable local courts for the time being. In the great majority of cases, trials at bar must have been always out of the question; and much more so, while the metropolis was a place talked of rather than known in remote counties, than at present. From the earliest times, therefore, the courts at Westminster could not dispense with justices in eyre travelling to the spot. These deputations of the supreme judicial power are necessary consequences of the strict doctrine of venue, and of the most latitudinarian extension which has yet been given to the original necessity of summoning a jury from the scene of action. The size of France more naturally led to great provincial institutions, like the old French parliaments, or the actual *Cours Royales*, with their divers subordinate jurisdictions. The different courts existing in England for different purposes, vary considerably in the number of their judges, and in the forms by which justice is administered. Mr Bentham praises single-seated judicature. Aristotle, on the contrary, insists that one or more colleagues are wise precautions against the moral or intellectual obliquities of a single individual. The practice of England offers a choice of every kind. The varieties are varieties of accident apparently, not of principle. Courts of equity, and most of the courts which do not proceed according to the common law, have always afforded, and still afford, only a single judge. But the number in the supreme common-law courts fluctuated considerably in former times. That of the Common Pleas, for instance, has been nine, seven, six, four, and five; of which latter number the three principal courts of common law consist at present. On the circuit the number drops down to one, both in civil and criminal cases. The trial of a peer for

Government and Laws.

felony takes place before the whole body of the nobility. The inferior courts vary equally. There are the manor and sheriff's court, with the crowd owing suit and service; the mayor and aldermen of corporations, assisted, or not, by their recorder; magistrates with summary jurisdiction, one or two in certain cases, up to the indefinite scramble of the bench at quarter-sessions. When members of a corporate body, and justices of the peace, render their judicial services gratuitously, the financial objection of a numerous judicature is removed. But it is only the financial objection; and a remuneration, more than adequate to the services performed, is likely to be often got in local influence, or some more objectionable shape. When the aggregate numbers stop short of letting in the passions which seize upon all large assemblies, even the majority may be yet likely enough to want the requisite character and knowledge. It is absolutely necessary to keep down this risk within certain limits. But the importance of interesting the higher and middling classes in the administration of justice may counterbalance in this instance, as in that of a jury, a small per-centage of errors.

If no very good cause can be assigned for the numerical varieties which appear upon the English bench on different occasions, it is perhaps still more difficult to give a rational account and justification of the distinctions by which the presence or absence of a jury is determined. The precise history of the institution, of its original object, and of the transitions through which it has passed to its present state, appears to be irrecoverably lost. But enough is left to show that it was a trial by neighbours, acting in the mixed capacity of witnesses, sometimes to facts, sometimes to character, as well as in that of judges ultimately determining the truth of the fact upon the result of the evidence. They were always the *patria*, but only in certain cases the *pares*, of the parties. As the law advanced to the dignity of a cultivated science, the line of demarcation between the facts which were to be proved, and the law which was to be applied to them, became strongly (occasionally too strongly) marked. If the temporary and casual inquest returned by the sheriff was recognised as the proper judicature for solving the question of fact, the permanent professional representative of the sovereign was alone competent to answer the question of law. The jury, growing up with, and itself a part of, the common law, was thus made the constant adjunct to its courts. It insured at all events publicity, without which every other excellence can give little security for real, and none for apparent, justice. Yet apparent justice is the source of the general confidence and satisfaction which forms one of the principal objects of government in all its branches. In their own limited departments, courts of equity, admiralty, and chivalry, arose under the civil law, and ecclesiastical courts under the canon law. Knowing nothing of a jury, they knew nothing of the above distinction; and the professional judge was of course entrusted with the decision both of fact and law. Cases in Chancery, where an issue is directed, are the mere exceptions of practice. There is nothing in the great majority of the questions which come before any of these courts, as compared with the civil questions which are tried at the assizes, to warrant a difference of this description. The interposition of a jury is matter of command in the one case, and of prohibition in the other; yet the rule rests only upon prescriptive usage, and not on reason. The legislature has often dispensed with juries, for obvious reasons. It is easy to understand how a jury is too popular an institution to be trusted with the administration of unpopular laws; such as laws enforcing rates, excise, and customs, must unfortunately always be. A more agreeable reason will justify the absence of a jury in some, but in some only, of the questions left to justices of the peace. Many causes are too free from difficulties, and at the same time too frequently recurring, to render it necessary or prudent to fill a jury box by means of a legal conscription on their account. Twelve citizens need not be summoned from the farm-yard or the counter to superintend the prosecution of all minor offences, and on every affair of correctional police. Whilst accidental circumstances have had the greatest share in establishing the distinctions by which in the higher courts juries are admitted or excluded, it would be as well to see in what cases some better criterion can be found. This would be wiser than the opposite courses which have been recommended by the extreme advocates of reform; an indiscriminate reception, or an almost indiscriminate refusal. A jury is an excellent tribunal for solving and appreciating ninety-nine out of one hundred of the combination of facts with which criminal justice has to deal. It is thoroughly qualified to determine all cases of intention, and assess almost all questions of uncertain damage, as in actions of libel and of trespass. Whatever abuses may stain certain periods of our history, the institution has well earned the traditional reverence with which it is regarded. It is entitled, on collateral accounts, to the respect of the lawyer and to the gratitude of the people. The distinction by which a question belonged to the judge or to the jury, according as it was a question of law or of fact, impressed a peculiar character upon our legal proceedings. It was the occasion of the remarkable simplicity and precision with which these separate questions were early discriminated in the English law. The national character of Englishmen has become remarkable for its almost judicial sobriety, and for the degree in which a deep sense of justice and an invincible respect for property are singularly combined with popular public spirit. How much of these, one or all, may be owing to the immemorial co-operation of the people in the administration of the law, is more than any one can presume to say. The impression left by English history on Jefferson is recorded in his declaration, that he would rather live without parliaments than without juries.

It is for the interest of the parties as well as of the public that a suit should be brought to a final termination as soon as a reasonable certainty for a correct decision has been secured. A government is bound to make its courts of original jurisdiction as good as, with reference to the circumstances of the case, it has the means of making them. That is the first and indispensable security. Supposing, nevertheless, that there are grounds for suspecting a failure of justice in any instance, on account of misdecision either upon the fact or the law, the course to be pursued depends on the stage which the proceedings have reached. There can be no reason for withholding from the original court, if it has still charge of the proceedings, the power of doing justice. This is done, in civil cases, in a court of common law, by means of a new trial. On the return of the record by the judges who were commissioned to take the trial at Nisi Prius, the court from which the record was sent can revise the law laid down at the trial by the presiding judge, and can also exercise a discretionary criticism on the verdict of the jury. In the event of the question being transmitted to a second jury, the judge commissioned to superintend, and the jurors summoned to rehear the facts, may be different individuals from those concerned in the former investigation; but the class which the inquest represents continues the same. It is not a superior court, but only another edition of the former. The judges on this occasion have frequently an opportunity of putting the parties to such terms as may appear to be advantageous to the ends of justice, especially with regard to the new evidence to be produced. It is a peculiarity belonging to the form of the action of ejectment, that a party may give himself the benefit of a new trial without the assistance of the court. In Lord Bath's case there had been five successive verdicts for Lord Bath before the House of Lords decreed a perpetual injunction. Justice Powell, in the year 1712 (1. Peere Williams, p. 212), observes that new trials from Nisi Prius are things of which he did not well know the foundation, but of which he had found the courts in possession. Judges of equity, possessing the whole case in their own hands, have allowed themselves a somewhat greater latitude of reconsidering and recalling their decrees, under the analogous forms of a rehearing and a bill of review. When an original court has once pronounced its final judgment, such a judgment is rightly made conclusive ever after, unless reversed by a higher court. There is sometimes the reality, and always the appearance, of hardship in binding the losing party to the possibly hasty or prejudiced opinion of a single tribunal. He will often be desirous of appealing elsewhere for the chance of its reversal. One chance of this kind, if the superior tribunal to which it is carried up is at all properly constituted, will be enough. This part of any possible judicial arrangement contains a choice of evils. Unless a power of removal or of appeal be given, one act of ignorance or of injustice will be fatal to the unlucky suitor. The other side of the risk is exemplified in the skeletons presented by the inferior courts for counties, hundreds, and baronies; or in a still more mischievous vitality. If the power is given, either both courts are really kept alive, in which case the temptation to run the gauntlet of both will often take a party through two proceedings, where he had much better have rested satisfied with one; or society and the law-books will be taxed with keeping up the cumbersome representation of a first court long after it has fallen into disuse. The differences between a writ of error from a court of common law and an appeal from the Court of Chancery are unimportant. They are the respective names by which the two systems mean the same thing. It is only upon appeals, in the spiritual court, that new evidence is received. The absurdity of the English practice, in marshalling appeals, consists not so much in its usually allowing an intermediate stage, as in its converting the whole nobility of the empire into the supreme appellate court. The barbarous incompetency of a tribunal of this nature is flagrant enough to satisfy the condition of raising an exclamation whenever it is mentioned; and it is neither removed nor concealed by the additional absurdity which, by way of a great constitutional improvement, imperatively requires at present, besides the one law lord who is to do the work, the ceremonial attendance of two suffragan peers in rotation for the purpose of looking on. A well considered reform has given the colonies and the spiritual courts an excellent court of appeal in the late judicial modification of the privy council. It is out of the question to suppose that suitors from the ordinary courts of the three kingdoms will rest contented without the benefit of some similar amendment in the character of the House of Lords as a court of justice. The scale of original and of appellate courts must be so constructed as to raise the presumption in favour of the latter. At present the appeal is carried from the most learned judicatures in the kingdom to one which necessarily knows nothing at all about the matter.

Criminal proceedings are carried on with or without a jury. The latter are called summary convictions. They were unknown to the common law. At present they take place in frauds on the revenue, and in many minor offences, before the particular persons appointed by the several statutes which have created these extraordinary jurisdictions. When the commissioner or magistrate has once pronounced his decision on the case as brought before him, he is *functus officio*. The privilege of appeal from his decision, in order to obtain a second inquiry into the merits, is not of common right; it only lies where it has been expressly given by act of parliament. The word is connected with the comparative novelty of the proceeding. For the word appeals had not passed beyond the spiritual courts until the time of James I. The earliest mention of appeals to the quarter-sessions is in the beginning of the reign of Charles II.; and towards the latter part of his reign they had come into general use. On the other hand, the writ of *certiorari*, by which the King's Bench removes before itself the proceedings of all inferior criminal jurisdictions, existed at common law. A certiorari has the object and effect of a writ of error, in an instance where, from want of learning, error was most likely to occur. For this purpose, whenever it is granted, the determination of the justices, like that of a jury in the case of jury-trial, is final as to the matter of fact; and the superior court, in reviewing their judgment, notices nothing but what appears upon the face of the conviction. The power of granting certioraris has been taken away by express statutory prohibition upon many occasions since the Revolution. Nevertheless the power is considered by the King's Bench as so beneficial to the subject, that the extent of these prohibitions is as much as possible restrained by the utmost jealousy of construction. A knowledge of law travels down to the quarter-sessions in the shape of opinions obtained from the metropolis, and in the persons of an attendant bar. If one or other must be dispensed with, it may perhaps therefore be fairly questioned whether the limited argument on a certiorari is not both more expensive, and at the same time less beneficial to the subject, than the more comprehensive re-investigation admitted upon an appeal. The conclusive nature of criminal proceedings before a jury depends on an absolute rule which the common law introduced, and which it has been able to preserve up to the present day in its own favourite tribunal. No man can be put in jeopardy twice for the same offence. As long as appeals for felony were in practice, this maxim might have been easily evaded. One precedent in direct contradiction to it is reported by Foster in the trials of the Jacobites. But when the jury has once been sworn on a charge within its jurisdiction, and upon a sufficient indictment, it is undisputed law that the prosecutor cannot elect to be nonsuited, and that there can be no second trial. The points on which a criminal judgment may be falsified or reversed by the King's Bench, or by the House of Lords, either with or without a writ of error, are all independent of the merits. Wherever the proceedings below are annulled on the supposition that the party prosecuted has never been tried at all, of course he still continues liable to prosecution in the same manner as if the former nominal trial had never taken place. The doctrine of attaints in criminal cases was at no time held in terror over a jury. At moments of violence, arbitrary judges, dissatisfied with a criminal verdict, formerly imposed fine and imprisonment instead. This was equally unjust, and was illegal into the bargain. In the nature of things, however, there can be no reason why the presumption in favour of the correctness of a verdict should be placed higher in criminal cases than in civil. Yet the one is left carefully open to revision, while the other is as carefully closed. The distinction is partly the result of accident, partly of indifference. But it is probably in some degree to be attributed to the fact that it was an object to bring litigation sooner to a close, where, owing to the poverty of the parties, and to the rules concerning the costs of an indictment, the litigation would be prolonged at the expense of the public.

The present popularity of the distinction is undoubtedly for the most part matter of tradition. The cause of it is to be found in the despotic practices of former times. The people gladly acquiesced in any rule which lessened the number of criminal prosecutions, and secured to a defendant the whole advantage which had been hardly earned for him by the rare contingency of a courageous jury. It is impossible that even the violent condition of unanimity can make the first impression of any court, especially of a court constituted like a jury, so completely satisfactory that the conclusiveness of a single verdict can be consistent in all criminal trials with the ends of justice. The rule in the present state of society operates entirely in favour of the prisoner. It must do so as soon as the crown has learned to exercise the prerogative of pardon on purely public considerations. Amongst these, and in the first rank, stands the necessity of protecting the conscience of mankind against the possible suspicion of punishing the innocent. If there has been any mistake in fact or in law, or if any fresh evidence has come to light, the prisoner is certain of receiving from the executive the full benefit of the discovery, in mitigation or pardon. On the other hand, unfounded acquittals are very injurious to the best interests of a community. They turn back on society offenders whom impunity has hardened. They embolden all who are tempted by vicious propensities to prey upon the public. They bear down the innocent man's appeal to a verdict in vindication of his character, by the cry of acquitted felons. They destroy the confidence of the people in the truth and efficiency of the law. The ancient scruples, by which the statutes of *jeofails* were not allowed to amend errors in indictments, had no connection with truth, justice, or sound humanity. As little can be said in behalf of any scruple which refuses society, for the punishment of a wrong-doer, the same assistance as it affords a private individual in satisfaction of his private injury. It will not be to the credit of the reason and the temper of the English public of the present day, if they are not able to remove this inconsistency between the two systems, by the interposition of checks and precautions, which, whilst they give a proper chance of justice to the public, shall secure a prisoner against any further hardship than that of having his case properly decided.

8. *Judicial Proceedings.*—On these points the English practice bears a remarkable resemblance to the Roman in some particulars, which have been comparatively abandoned in countries where otherwise the civil law is the principal authority. It is the more curious to find these coincidences between two systems, which are otherwise so different, that Selden observes they have not a term in common. The original writs of the common law, by being the tests whether a party has or has not a right, are rude approximations to a code. Their analogy to the set forms for actions adopted by the Romans is so striking, that Duck and Noy agreed that the writs in the *registrum brevium* must have been settled by great civil lawyers. Blackstone (vol. iii. p. 117) speaks as if some similar standard was in itself undoubtedly necessary to fix the true state of a question of right; and he even subjoins, that an equivalent method is recognised by all the modern legislatures of Europe. This is surely a proposition very difficult to be maintained in the presence of the contrary experience, both of Scotland, and of the English courts of equity and of Doctors' Commons. In the subsequent proceedings, most judicatures leave the parties to tell their story in their own fashion. But Mr Stephen, in his excellent work on pleading, shows, by reference to Quinctilian's account of the method of oratorical analysis, which he himself used in forensic controversies (B. vii. c. 1), how artificially the logic of a Roman advocate was directed to the object of bringing out the point in issue. Looking at the different ways in which the testimony of witnesses may be extracted, Mr Bentham says that cross-examination is, both in the thing and in the name, peculiarly English; for every thing of the sort is excluded by the interchange of written interrogatories from the present usage and vocabulary of the civil law. However, in the seventh chapter of the fifth book of his Institutes, Quinctilian has again sketched as accurate a picture of examination and cross-examination as a Nisi Prius leader could desire. Every rule of positive law is necessarily founded on a balance of advantages and disadvantages. In many cases the line of prudent compromise between opposite mischiefs is extremely difficult to draw and to preserve. Wherever the line is taken, nothing is so easy or so unreasonable as to caricature it, by representing only the inconveniences which every compromise assumes. This is particularly true with regard to judicial pleadings. They are merely the statement made by both sides of their case; nevertheless they are a subject which, on account of the opposite mischiefs of the Scottish and English systems, has lately been the occasion in both countries of elaborate debate and judicious propositions for their reform. The nature of the mischiefs in these two instances is just the reverse of what might have been expected. Scotch pleadings, which were carried on under the superintendence of the judge, erred by extreme looseness; whilst English pleadings, which, except in extreme cases, had been for ages left to the discretion of counsel, became celebrated for the characteristic error of an extreme strictness and technicality. The intermediate course taken by the Court of Chancery appears upon the whole to be the most rational; though equity drawing has quite reproach enough in its verbosity and repetitions, where every word has a pecuniary value. As soon as the new rules relating to pleadings, which have been lately framed by the judges of the superior courts of common law, shall have come into practice, it may be confidently trusted that the common law will no longer labour under the evil of voluminousness, in addition to that of technicality. Originally, parties made their statements to the judge by word of mouth, with as little form as a complainant tells his story to a magistrate, or as counsel at present open the case orally at the bar. During this period a great deal would depend on the talents of the judge for abridging irrelevant details, and clearing up ambiguous expressions. Afterwards, towards the middle of the reign of Edward III. when writing became common, the substance of the altercation, to which the evidence and the argument were to be applied, was required (and very properly) to be put down in writing in the first instance. The moment of this transition was the golden age of English pleadings. Serjeants drew them, and judges settled them. The judges ceased by degrees to interpose at this early stage of the suit. But, according to the scholastic subtilties of that age, the science of special pleading was encouraged to become more minute and complicated. A proportionate degree of technical knowledge was rendered necessary for the judge, since he had ultimately to award the prize to the professional combatant who had manœuvred on behalf of his client with most success on this preliminary arena. Fitzherbert, Littleton, and Coke expatiate on the learning, the lucrativeness, the honour, and delights of pleading. The reports of Chief-Justice Saunders are the glory of this art; and his mind is a model of the sort of astuteness which it cultivates. The department calls for but a small, and that far from the highest, portion of real judicial ability. It becomes only prejudicial craftiness the moment that it passes the boundaries within which a strong and logical understanding would confine

the speeches of advocates at the bar. The degree at which an intimate acquaintance with special pleading still ranks in the list of qualifications for the bench, is a proof how much that boundary has been overpassed.

Besides mastering the merits of his case, formal difficulties of great magnitude are in this early stage of the inquiry thrown upon an English lawyer. In the first place, he has to select the appropriate form of action; and having done that, he must comply with the established principles on which the forensic argument is to be conducted, and which, *mutatis mutandis*, are equally applicable to all forms. Our historical sketch of the transitions of English pleadings shows what alone they ought to be when they are properly considered. If they are nothing but the statement made by the parties, of their respective cases, What is the only object of an intelligent and honest statement? It can be nothing else than to keep clear of extraneous topics, and to get to the point in dispute as soon as possible. As every legal question consists of the application of a supposed principle of law to some one or other supposed fact, the first thing to ascertain is, About what are the parties quarrelling? Do they differ in their view of the law or of the facts, or both? The alternative cases present no difficulty. When there is no dispute about the facts, there is a simple point of law for the opinion of the judges. It is at once raised upon what is called a demurrer. On the other hand, when the dispute turns entirely on the facts, what is wanted, is, that they be brought out to the jury in so precise and definite a shape, that it is impossible to mistake the point or points in issue. If the party is prepared to dispute the correctness of the law as applied to the supposed facts, and further, also the correctness of the facts as stated, questions of considerable difficulty and difference of opinion open on him. Must he enter upon both issues simultaneously? or may he take first one, and then the other? and, in the latter case, with which of the two issues, that of fact or that of law, ought he to begin? The English common law disposes of these considerations by summarily making an admission of the facts a condition of a demurrer. A legal proposition can seldom be put forward so manifestly erroneous that a defendant will not think it advisable to retain both chances in his hands. It is on the facts, namely, what he should prove, concede, deny, that he must be careful to watch over his own interests. Points of law will comparatively take care of themselves, and the benefit of these is also secured at all stages. Demurrers are freed in courts of equity from the above condition. The experience in equity by no means justifies the apprehension entertained by the common-law pleaders, that on the removal of the condition every cause at common law would be forthwith burdened with a tentative demurrer. The discretionary application of costs might easily be made a most effectual instrument for the suppression of such unwarrantable speculations as might at first arise upon a relaxation of the former rule. The abuses of special pleading have on many occasions induced the legislature to interpose. Particular defendants, as magistrates, for instance, have been favoured, by way of exception, with the privilege of pleading the general issue; that is, they are allowed to deny generally the wrongful act imputed to them, without being called upon to state whether they mean to deny the law or the fact, or to mention a single item of the hundred possible special grounds of their defence. The English system prides itself on its peculiar mechanism, every movement of which necessarily tends to a clear and single point. The plea of the general issue does much more than lose the advantage for which so much is sacrificed. It covers every thing with a cloud. It gives the defendant the privilege of evading the duty of speaking out, by adopting a common form, which tells the opposite party absolutely nothing. The regulation which refuses a prisoner a copy of his indictment till he holds up his hand to take his trial, is scarcely in principle more unjust. Fraud lies in generalities. On the one hand, a defendant or a prisoner has a right to know the particulars of the demand or of the accusation brought against him; something more than the mere assertion, that he is liable to a demand or charge of some sort; what it is being left to appear on the day of trial. On the other hand, plaintiffs and prosecutors are equally entitled to know beforehand the particulars of the defence on which their claim is to be resisted; something beyond a direct negation. At all events, when the power of pleading the general issue is thrown over a party as a shield, the exception should rest on the nature of the case, and not on the authority of the person. A better distinction might be found than that of official station. Pleadings drawn up and communicated by the professional representative of the parties ought to contain a correct narrative of the transaction in writing. Thus prepared, they might be expected to be more complete, and at the same time more relevant and more concise, than any judge could have obtained from their own mouths if present. Yet what would be thought of parties in open court who were to ramble into the jargon and exaggeration of a declaration; or who should indulge themselves *viva voce* in the fiction of alleging the utmost preciseness of time and place, whilst every syllable of the allegations was perhaps notoriously and ridiculously untrue. It is difficult to account for the origin of such extravagant falsehoods. They are as indefensible in point of reason, coming from the pen of a pleader, as if they came from the principal himself, preferring his claim and conducting his cause in person.

9. *Evidence.*—What the pleadings have stated, it is the object of evidence to establish. One of the most difficult things to account for, is the absurdity of the rules of judicial evidence, which have prevailed in all ages and over all countries. Sir William Jones observes, in his preface to Isæus, that "we may triumph in our elegant and philosophical theory of evidence, which Aristotle and Plato must have admired, and by the strict rules of which all trials in the world ought to be directed." No panegyric was ever less deserved. It is perhaps true that the English theory on this subject is less objectionable than the theory of almost any other country, inasmuch as its exclusions appear upon the whole to be fewer and more strictly limited. But it is faulty enough even in this respect; whilst whatever other defects may be found incorporated in its principles, they are likely to be felt more severely in practice, in consequence of the unbending rigidity with which every rule is enforced by English lawyers. Our judicial system is too careless in requiring or preserving preconstituted written evidence, even in the case of recurring events and deliberate transactions. The registries of baptisms, deaths, and marriages, are still left as a part rather of ecclesiastical discipline than of civil obligation. They are exposed to great irregularities and losses, whilst a general registry of deeds remains yet to be established. In criminal proceedings the attendance of witnesses on both sides is secured by summary methods. The duty of appearing for a prisoner as well as against him is equally a debt due to society by its members; although it is one which the law was disgracefully slow in recognising. In civil cases witnesses are obliged also to attend; nor can they insist upon more favourable terms than the tender of their expenses. The English law admits of four heads of personal incompetency in a witness: one intellectual, as want of sufficient reason; and three moral. Of these, the first is a want of religious belief, extending as far as to disbe-

lieve the existence of a God and of a future state of rewards and punishments. The second is infamy of character, evidenced by a judgment of felony, or for some offence considered by the law as infamous. The last is, a direct legal interest in the cause at issue, or in the question asked. The objection that the witness might use the verdict upon some future occasion, has recently been removed. The only head of incompetency from family relationship, is the case of husband and wife. It applies to both, and to evidence offered either for or against each other. The only instance of incompetency from professional relationship, is the rule by which a lawyer is prohibited from giving evidence against his client concerning any facts with which he has become acquainted under the sanction of that relation.

The objections are equally fatal, whether the acts to which the testimony applies are sudden or deliberate. It would be as difficult to justify the want of distinguishing between these two classes, as to prove the propriety of the distinctions which, in some instances, prevail between the admissibility of the same evidence in criminal as in civil proceedings. The rejection of hearsay is also too extensive. It may be doubted whether the rejection should ever be carried further than to declarations made by a person whom it was possible to have produced as a witness, and who might have been compelled in the character of a witness to repeat his supposed statement under the sanction of an oath or other solemnity, and subject to cross-examination. It does not apply to declarations, themselves a part of the transaction. The tendency of the judges of latter days has strongly run in the direction of letting in evidence. But more extensive innovations upon the former exclusions than the judges feel at liberty to authorize are probably near at hand. Amongst these, the taking away the exclusion on the ground of interest in a civil suit, is the most important. There can be no doubt but that the examination of a prisoner, humanely conducted, would be very favourable to truth. But there is much doubt whether even an open court could be trusted with the authority, and still more whether the public would be satisfied with the change. All the objections above enumerated go to the competency of a witness, and, where they apply, are fatal. All other objections are of minor consequence. They go only to the credit, and as such, they are questions, not of total exclusion, to be determined by the judge; but matter for observation, turning on degrees of credit, more or less, to be weighed by the jury. Two witnesses, or an equivalent, are universally required by the civil law. With us, one witness, if believed, was sufficient for all purposes, until parliament made two necessary in treason, and until a rough sort of comparative arithmetic established the demand for something more than a single witness upon a charge of perjury. Parliament has insisted upon the aid of three witnesses to a will devising an acre of land, though a million in the three per cents. may be bequeathed by an unwitnessed testamentary paper. Courts of equity have imposed a limit on their encroaching jurisdiction, by allowing the positive oath of a defendant to be conclusive against the unsupported testimony of a single witness. The limit has probably a reference to the double origin of Chancery; first as a court of conscience, and next as more closely connected with the civil law. There are but few instances, and those introduced by act of parliament, where written evidence is of absolute necessity. The policy of the celebrated statute of frauds was adopted from the French ordonnance of Moulins; and it admits of no exceptions where it applies. But writing is often used by the parties in transactions which are without the statute. The common law is equally strict in both cases, in preventing written instruments from being varied, added to, or explained by *parole*. The rule has been broken in upon to a certain extent, by a distinction between *ambiguitas patens et latens*, of which Lord Bacon has the credit. The best justification to be made for the exception which allows an ambiguity raised by external evidence to be also removed by external evidence, appears to stand on the following considerations. It restrains the fear of perjury within a much narrower circle. In the next place, the author of the writing had not equal means of protecting his intentions against an ambiguity of this description. The admissibility of copies is tried by the paramount rule, that the best evidence in existence must be produced. Mere declarations acquire no further validity by being committed to writing. They thus become only written hearsay. The mode of extracting oral testimony varies according to the courts in which it takes place. Very little can be added to the excellence of the system in the courts of common law. A witness there delivers his evidence *viva voce*, in the presence of the public, of the parties, and of the deciding judge. There is scarcely a limit to the range of examination and cross-examination, but the discretion of the court. The practice in courts of equity is much more imperfect. The examination being conducted on written interrogatories, and by examiners out of court, loses all the advantages of *viva voce* suggestions on the spot, of cross-examination, and of publicity. The very demeanour of the witnessess is removed from the observation of the judge who has finally to determine on their credit. The proof of writings depends on the nature of the instrument, or on the mode of its execution. The English law does not affect to create a scale by which the value of particular evidence may be determined. With the same forbearance, it has refrained from establishing any judicial standard concerning the amount of evidence which is or is not adequate grounds for a judicial determination in any cause. These are questions of fact, on which (beyond a few hints, more valuable to a committing magistrate than to the deciding judge) the less that is said in law-books the better. The only security for correct decisions is the founding competent tribunals, and binding them to no other criterion than that of their own personal conviction. Mr Bentham's work on evidence, and his criticism on this branch of the English law, are perhaps the most original, and at the same time most useful, of all his writings.

10. *Judgment and Execution.*—The object of a civil action is either the recovery of a right certain, for instance, particular lands, specific goods, a fixed sum as settled by the agreement of the parties; or the recovery of uncertain damages, more or less, according to the extent of the injury which the plaintiff shall be able to prove that he has sustained. The first class of cases, by the nature of the demand comprehended in it, relieves the tribunal from the vague and discretionary inquiries arising under the second. The amount of damage is a fact which a few impartial individuals taken from the body of society are in the great majority of cases peculiarly qualified to assess. This in civil actions is accordingly the province of the jury. They are likely to be far better acquainted than learned judges with the real elements on which the calculation ought to proceed. Damages evidently so excessive as to be explained only by the imputation of gross ignorance or corruption, are, however, one of the admitted grounds for sending back the case to a second inquest. The judgment against Titus Oates, for *scandalum magnatum*, at the suit of the Duke of York, where one of the juries of those days had assessed the damages at L.100,000, was reversed after the Revolution. The costs of a trial were never given at common law. In most cases, however,

Government and Laws.

they have for a long time followed as the ordinary incident to judgment. Since the preliminary oaths and pledges of former days have fallen into oblivion, they constitute the only security of the defendant against frivolous and vexatious actions. Costs are too material an item in litigation to be properly bound in any court by one uniform rule. We are not disposed to recommend, for the sake of consistency, that courts of equity should be brought under the strictness. It would be a better approximation that the discretion of the courts of common law should be assimilated to the latitude which courts of equity have assumed. It is easy to enlarge the statutory power given in some instances to judges' certificates, or to grant an analogous authority to the jury. Certificates for costs might be made a sufficient restraint on fraudulent attempts against the credit of the law and the interests of society. There are occasions when personal vindictiveness combines unnecessarily an indictment and an action in misdemeanors, or when base practitioners multiply actions for the sake of costs against several parties who happen to be all legally liable. In ejectments, trespasses, libels, joint-stock companies, and all cases where many rights depend upon a single title, or the ends of justice may be satisfied by a single verdict, the law in its present state may be far too easily and too profitably abused.

In consequence of the feudal restraints on the alienation of land during a great period of English history, it continued to be only partially liable for its owner's debts of any description, and was not liable at all for ordinary debts by simple contract. The restraint went far beyond the policy of entails. To the extent that entails were permitted, a tenant for life might, as far as the principle was concerned, have bound the life estate, but nothing more; since that only is his own. This invidious protection of land, even when owned in fee against simple contract creditors, has been completely removed during the last session. Ever since the 29th Charles II., whenever land was at all liable, it was equally so although held in trust for the debtor, as when it was held in his own name. No feudal principle interfered to protect personalty from a creditor. Nevertheless, the absurd expression, that money cannot be sold, and the maxim, so inconsistently evaded in many cases, that a debt or a right to sue another was not transferable, had an equally mischievous effect. No sensible reason can be assigned why the principle of foreign attachment should exist for the benefit of the citizens of London only, and not for the benefit of every creditor in England. There is even still less reason why funded property should be placed beyond the reach of the law, on the technical distinction arising from its subsisting in the form of an annuity payable by the nation to the holder of the stock. The bank, in the management of this property, is a parliamentary trustee for the owners of it. And the judgment of a court of law, duly certified on a recovery against a stockholder, ought to have the same effect as the signature of the accountant-general of the Court of Chancery for authorizing a transfer of the stock. There is a dangerous tendency in facilities for credit to run to too unlimited an extent. The power of imprisoning the person encourages this tendency; and, what is worse, it is frequently resorted to in the hopes of laying the innocent relations of a spendthrift under contribution. The humanity of modern times has thrown open the doors of the debtors' gaol, by discharges under the insolvent act. The security contingent on the person of a debtor was good for much at no time. In its actual state, it is of far too little value to be worth contending for. It is likely to be soon reduced to nothing, since it is seriously proposed, on grounds of public policy, to prohibit altogether imprisonment for debt.

For the prevention of crimes, the law seeks to obtain a counteracting influence in all directions; in its command over property, character, liberty, and life. The jury find merely the fact of guilt. The legislature has to most offences affixed a *maximum* of punishment, according to a rude calculation of the nature of the offence and the interests of society. In a very few a *minimum* also is enacted. The power of arbitrating between these extreme limits, and of mitigating the penalties where no limit has been prescribed at the bottom of the scale, rests entirely with the judge. The gradation of punishments seems to call for further revision, with the object of proportion, mitigation, and precision. The calculation of public damage proceeds on the principle of prevention, and is set apart for the judge; that of private damage looks only to the satisfaction of the party, and belongs to the jury. The distinction arose probably on totally different grounds. It may be justified, however, by the observation, that the calculation in the instance of crimes does not depend on the individual case, but on a more comprehensive and general view of the bearings of the whole criminal law than a jury can well be qualified to take; and that a greater chance is thus afforded of an approach to that uniformity or average which it is so desirable to obtain. Pardon is a prerogative properly left with the executive. This is so in America, notwithstanding the foolish denial of the possibility by theoretical writers against republics, equally as in England. The exercise of the prerogative is of course greatly influenced by the recommendation of either the judge or jury. The abuse of it in favour of particular criminals was one of the scandals of many reigns. This had reached so extravagant a pitch, that Sir Thomas More praises Henry VIII. on the ground that never king granted so few. Nevertheless, such was the complication and severity of the law, that to execute it according to its letter would have been not only unpopular, but impossible. At the very period when particular pardons were a national grievance, general pardons were looked forward to as public blessings. It is observed by Sir Bartholomew Shower, that there were never five years without a parliament pardon, and that eleven were published by Elizabeth. "These," he says, "it was which made parliaments and crowns the darlings and the desire of the people." The dispute whether the crown can pardon on impeachments, was one of the remains of the jealousies of former days. It was raging, as a great political question, as late as the Revolution; and it is still open to argument as a point of law. The dissolving parliaments to save his favourites from impeachment, is charged even by Clarendon upon Charles I. as a denial of justice to the nation. There is a vast variety of writs of execution in civil suits of the most trifling moment. By way of contrast, Blackstone notices the slightness of the form by which a marginal note put by the judge upon the calendar, is the sole authority for the sheriff, even in a capital conviction. It is one only of many instances of the comparative value set by our ancestors on the formal administration of civil and criminal jurisprudence. The execution of the law in all cases, of whatever description, is intrusted to the official representatives of the executive. Special jurisdictions have their special officers; but, by the common law, the sheriff is in all judicial matters the proper minister of the crown.

ENGLISH LANGUAGE. When the Romans invaded the south of Britain, they found the country possessed by a people of Celtic origin, and speaking a dialect of the Celtic tongue. This invasion took place about fifty-five years before the birth of Christ, and the invaders retained their ascendancy till the commencement of the fifth century. During this interval, the Romans imparted to the rude natives some tincture of their own intellectual refinement, but must have left the British language as they found it: the foreign settlers were not sufficiently numerous to produce any change in the speech of the original inhabitants. When the huge fabric of the Roman empire began to decay, the Britons, who had the advantage of a remote and insular situation, found means to assert their independence. They however divided themselves into many petty states, and exercised many petty animosities, which impaired the national strength, and rendered them an easy prey to foreign invaders. The pirates of Saxony had long been accustomed to make occasional depredations on their coasts. The Picts and Scots, that is, the Goths and Celts of North Britain, infested them on the frontier; and at length the sense of common danger produced some degree of union in their councils and exertions. In this condition of their affairs, the Saxons obtained a permanent footing in the country. In the year 449, Vortigern, king of the Britons, had recourse to the aid of Hengest and Horsa, who first appeared as allies, but were soon converted into the most formidable enemies.[1]

The Saxons, like other Gothic tribes, derive their origin from a mighty horde which wandered from the east, and gradually overran the best portions of Europe. So early as the time of Ptolemy the geographer, this particular tribe had proceeded as far to the westward as the banks of the Elbe, and their primitive seat was between that river and the Eyder. Although at first they were not very formidable for their numbers, they gradually obtained a powerful ascendancy in Germany. Towards the middle of the third century, they entered into a league with the Franks for the purpose of opposing the Roman arms; and they afterwards enlarged their connexions and increased their influence till it predominated in a territory of great extent, reaching from the Eyder to the Rhine. This wide tract of country was not entirely peopled by Saxons: it included various nations, united by the ties of a kindred origin, and actuated by a sense of common interest or danger; but such was the ascendancy of the Saxons that they communicated their name to the entire confederacy, which, among other nations, comprehended the Jutes, who inhabited the south of Jutland, and the Angles, who inhabited the adjacent district of Anglen. Hengest and Horsa, the leaders whom we have already mentioned, were not Saxons, but Jutes. The subsequent emigrants were for the most part Angles, and their descendants were long distinguished by the name of Anglo-Saxons. The first part of the name denotes the predominant tribe, the second denotes the original relation of that tribe to the Saxon confederacy. The new country which they acquired was denominated Engla-land, or the land of the Angles. These German invaders established themselves in the most fertile districts, and gradually displaced the Celtic inhabitants, till at length they were chiefly confined to the fastnesses of Wales, where the prevalence of the ancient language still indicates the continuance of their race. Eight new states were formed by the Anglo-Saxons, who maintained their independence till the year 1016, when they were subjected to the yoke of a Danish conqueror. Canute, and his two sons, Harold and Hardicanute, reigned in England for the space of twenty-six years. A Danish court, and a Danish army, with other settlers, must have had some influence on the common speech, especially as the language of the conquerors was not very dissimilar to that of the conquered. But the laws and other public documents continued to be written in the Saxon tongue, and this new dynasty soon finished its course. The Saxon line of kings, which was restored in 1042, terminated in 1066, when Harold the Second was slain at the battle of Hastings, and William duke of Normandy ascended the throne of England. The Saxon dominion had thus continued for the best part of three centuries; and as the great body of the people was still of this race, it is obvious that their national language must have survived their political power. A writ in the Anglo-Saxon tongue was issued by Henry the Third, who began his reign in the year 1216.

In the language spoken by this ancient people, a great variety of literary reliques has been preserved. "The Anglo-Saxon literature," says Professor Rask, "possesses in many respects, even for its own sake, no small degree of interest. The numerous ancient laws throw considerable light upon the laws of the old Germans and Scandinavians, as well as upon their customs and civil institutions. The old chronicles and genealogies are important sources for the ancient history of the Low German and the Scandinavian nations. The various documents illustrate much in English history. Even the theological remains, shewing the constitution and doctrine of the ancient church, are not devoid of value for ecclesiastical history, especially to the modern English and Scottish churches. The translation of several parts of Scripture may likewise be advantageously employed in biblical researches. But of all, the poetical pieces are the most interesting, especially the great Anglo-Saxon poem in forty-three cantos, published at Copenhagen in 1815, by the Royal Archivarius G. J. Thorkelin,[2] which, from its commencement, he has aptly entitled *Scyldingis*. This is perhaps the only Anglo-Saxon piece possessing value on account both of its matter and style, particularly for the nations of the north; the principal hero being Swedish or Gothic, though the action lies in Denmark."[3] This ancient poem, more generally known by the name of *Beowulf*, has been translated into Danish verse by Dr Grundtvig, and ably illustrated by Mr Conybeare.[4]

The language of the conquerors became the language of the king's court and of all the courts of law. The pleadings of counsel and the decisions of judges were couched in a dialect which is commonly described as Norman French, but which in the mouths of English lawyers became utterly barbarous; and more curious specimens of composition are scarcely to be found than those which occur in the reports of cases written in a jargon half-French half-English. Lawyers have in all ages been conspicuous for their stiff adherence, with or without reason, to those forms and maxims in which they themselves have been duly trained. Long after French had ceased to be the language of legal proceedings, they adhered to the practice of reporting cases in the motley dialect used by their predecessors; for, as Blackstone remarks, "the practisers being used to the Norman language, and therefore imagining that they could express their thoughts more aptly and more concisely in that than in any other, still continued to take their notes in law French; and of course, when those notes came to be published, under the denomination of reports, they were printed in that barbarous dialect; which, joined to the additional terrors of a Gothic black letter, has occasioned many a student to throw away his Plowden and Littleton, without venturing to attack a page of them."[1] By the 36 Edw. III. c. 15. it was enacted that for the future all pleas should be pleaded, shewn, defended, answered, debated, and judged in the English tongue, but should be entered and enrolled in Latin. The statutes of the realm long continued to be promulgated in French; and it was only from the accession of Richard the Third that Englishmen were governed by laws written in their native tongue.

[4] Conybeare's Illustrations of Anglo-Saxon Poetry, p. 30. Lond. 1826, 8vo.

The Norman conquest proved fatal to the entire race of Anglo-Saxon nobility, many of whom lost their lives, and almost all of them their property. Not a few of the number sought refuge in different monasteries. Some of them became abbots, and others closed their career as monks. The lands of the Saxon earls were occupied by the Norman barons, who found it necessary to consult their personal safety by inhabiting fortified towns and castles. They must have had but little intercourse with their vassals, whom they probably did not respect, and whom they had much reason to fear. They retained their native tongue, and seldom acquired any other. For a long period of time, the peasantry continued unmixed with foreign settlers: they continued to cultivate the same soil; and when the written language of the kingdom had received many foreign accessions, the rustic dialect preserved its primitive elements with very few material changes. Much of the patois of different countries consists, not in adulterations of the modern, but in remnants of the ancient language. Many Anglo-Saxon words and idioms, unintelligible to persons of a refined education, are still current among the rural population of particular districts of England.

The English monarchs of the Norman race were liberal patrons of such literature as they themselves understood. French poetry seems to have been much relished at the court of England; and, according to a very competent judge, M. de la Rue, it was from England and Normandy that the French received the first works which deserve to be cited in their language. The works of many Anglo-Norman poets have been preserved, and they certainly form a curious subject of literary research. In this department, a learned lady, Marie de France, makes a prominent figure. Her poems have been recently edited by M. de Roquefort; and one of the historical poems of Wace still more recently by M. Pluquet. A history of the Anglo-Norman poets and poetry is speedily expected from M. de la Rue, who has already exhibited sufficient evidence of his being well qualified for such an undertaking.

Of the language spoken by the great body of the people about a century after the conquest, the reader may in some degree be enabled to judge from the following specimen of Lyamon's translation of Wace's *Brut d'Angleterre.* The translator describes himself as a priest of Ernlye upon Severn, and he is supposed to have completed his task about the year 1180.

Tha the masse wes isungen,
Of chireeken heo thrungen.
The king mid his folke
To his mete verde,
And mucle his duȝethe:
Drem wes on hirede.
Tha quene, an other halve,
Hire hereberwe isohte:
Heo hafde of wif-monne
Wunder ane moni en.[2]

"When the mass was sung, out of the church they thronged. The king amid his folk to his meat fared, and many of his nobility: joy was in the household. The queen, on the other side, sought her harbour (or lodging): she had wonderfully many women." Here, and in a much more ample specimen of the same work, we perceive no mixture of French words. The idiom is essentially Anglo-Saxon, but with some indications of its being already in a state of transition: the vestiges of the language, in its more modern form of English, may be distinctly traced. Of the language in a state more considerably advanced, we find a specimen in a facetious poem published by Dr Hickes.

Far in sea, by West Spain,
Is a land ihote Cokaygne,
There n'is land under heaven-rich
Of wel of goodness it y-like.
Though Paradise be merry and bright,
Cockaygne is of fairer sight.
What is there in Paradise
But grass, and flower, and green rise?
Though there be joy and great dute,
There n'is meat but fruit;
There n'is hall, bure, no bench,
But water mannis thirst to quench.[3]

In this poem, which apparently belongs to the thirteenth century, we perceive a further deviation from the Anglo-Saxon idiom. In the preceding extract, the obsolete spelling is not retained, and the language is thus rendered more intelligible. The subsequent quotation is from a metrical history of England, written by Robert, a monk of Gloucester, who appears to have lived about the year 1278. This rhyming chronicle, as Mr Warton has remarked, is totally destitute of art or imagination. The author thus describes the island of Ireland, nor does he fail to mention its exemption from venomous reptiles.

Yrlond ys aler yle best with oute Engelonde.
The sea goth al abouten hym eke as ich vnderstonde.
More he ys than Engolond, and in tho south half he ys
Bradder and more of ynow than in the north ende y wys.
Aȝeyn the lond of Spayne he stond in the north syde ryȝt.
Selde snowe ther inne lith, and nameliche thre nyȝt.
So euene hot that lond ys, that men durre selde
Here orf in howse awynter brynge out of the felde.
Lese lasteth ther al the wynter: bute hyt tho more wonder be,
Selde me schal in the lond eny foule wormes se:
For nedres ny other wormes ne mow ther be noȝt;
And ȝef he beth thider bi cas from other landes y broȝt,
Heo dyeth thorȝ smel of the lond, other thorȝ towchyng y wys:
Eche gras that ther inne wexeth a ȝeyn venym yt ys.
For men that ben venymed, thorȝ grases of Yrlond
Y dronke he beth y clansed sone, thoru Godes sonde.
Hony and mylk ther ys muche, mony folk and bolde.
This ys the stat of Yrlond, as iche habbe y tolde[4]

Another chronicler, who however belongs to a period somewhat more recent, was Robert Manning, more commonly called Robert of Brunne. He has himself stated that he had resided fifteen years at Brunne, or Bourne, in the priory of black canons, when, in the year 1303, he began his translation of Grosteste's *Manuel des Pechés.* This version still continues in manuscript; but one portion of his historical work, his translation from Langtoft, has been edited by the indefatigable Hearne, who rendered a similar service to Robert of Gloucester. The inedited portion consists of a translation from Wace's Brut. Peter Langtoft was an Augustine canon of Bridlington in Yorkshire, and is supposed to have died in the reign of Edward the Second. The subsequent passage relates to Sir William Wallace.

Whan Sir Jon of Warene the soth vnderstode,
That the Waleis gane brenne, an oste he gadred gode,
And went to Struelyne agayne Waleis William,
Bot the erle with mykelle pyne disconfite away nam;
And that was his folie, so long in his bed gan ligge,
Untille the Waleis partie had vmbilaid the brigge:
With gauelokes and dartes suilk ore was non sene,
Myght no man tham departe, ne ride ne go bituene.
Thore first tham tauht how thei did Fawe kirke:
Alle gate the brigge he rauht, of nouht our men were irke.
Whan the erle herd say, the brigge how William toke,
He douted to die that day, that bataile he forsoke.
The Inglis were alle slayn, the Scottis bare tham wele,
The Waleis had the wayn, als maistre of that eschele.
At that ilk stoure was slayn on our side
God men of honour, that wald to the bataile bide.[1]

A more curious specimen of composition is to be found in the Vision of Piers Plowman, which appears to have been written about the year 1362, and which is commonly ascribed to Robert Langland, a secular priest. The work, which comprehends a series of visions, is replete with satire on the different orders of men, especially on the clergy, both regular and secular; but it is likewise diversified by a succession of incidents, and furnishes abundant evidence of the author's talents for description. His mode of versification is not unworthy of particular notice. Alliteration supplies the place of rhyme: the corresponding sounds are at the commencement, not at the termination of words. Our extract from this remarkable work must necessarily be very brief.

And to the church gan ich go, God to honourie,
By for the crois on my knees knocked ich my brest,
Sykinge for my sennes, segginge my pater noster,
Wepyng and wailinge tyl ich was a slepe;
Thenne mete me moche more than ich by for tolde
Of the mater that ich mete fyrst on Malverne hulles.
Ich sawe the feld ful of folk fram ende to the other,
And Reson revested ryght as a pope,
And Conscience his cocer by fore the kynge stande.
Reson reverentliche by for al the reame
Prechede and provede that thuse pestilences
Was for pure synne to punyshe the puple,
And the south west wynd on Saturday at eve
Was pertliche for prude, and for no poynt elles.
Piries and plomtrees were poſſed to the erthe,
In ensample to syggen ous we sholde do the betere:
Beches and brode okes weren blowe to the grounde,
And turned upward here tayl, in tokenynge of drede
That dedlych synne er domys day shal for do us alle.[2]

After these specimens of verse, we shall exhibit a specimen of prose, selected from the seventh chapter of the Acts of the Apostles, as translated by John Wycliffe. The translator, who was born about the year 1324, and died in the year 1384, may be regarded as the father of English prose. He was the author of various works in Latin as well as English; but the most important of his literary labours was a complete version of the Scriptures. He was the great precursor of Luther, who appeared after an interval of one hundred and fifty years; and it may perhaps be safely affirmed, that to him the cause of reformation was more deeply indebted than to Luther himself.

"This Moises ledde hem out, and dide woundris and signes in the lond of Egipte and in the Reed See, and in desert fourti gheeris. This is Moises that seide to the sones of Israel, God schal reise to ghou a prophete of ghoure britheren; as me ghe schulen heere him. This it is that was in the chirche in wildirnesse with the aungel that spak to him in the mount Syna and with oure fadris, which took wordis of lyf to ghyue to us: to whom oure fadris wolden not obeie, but puttiden him awei, and weren turned awei in hertis into Egipte, seiynge to Aaron, Make thou to us goddis that schulen go bifore us; for to this Moises that ledde us out of the lond of Egipte, we wite not what is don to hym. And thei maden a calf in tho daies, and offriden a sacrifice to the mawmet, and thei weren glad in the werkis of her hondis; and God turnyde and bitook hem to serue to the knyghthood of heuene; as it is writen in the book of prophetis, Whether ghe hous of Israel offriden to me slayn sacrifices, either sacrifices of oostis fourti gheer in desert? And ghe han take the tabernacle of Moloch, and the sterre of ghoure god Renfam, figuris that ghe han maad to worschipe hem: and I schal translate ghou into Babiloyne. The tabernacle of witnessyng was with our fadris in desert, as God disposide to hem, and spak to Moises, that he schulde make it aftir the fourme that he saigh: which also oure fadris tooken with Ihesu, and broughten into the possessioun of hethene men, which God puttide awei fro the face of our fadris til into the daies of Dauid, that foond grace anentis God, and axide that he schulde fynde a tabernacle to God of Iacob. But Salamon bildide the hous to him. But the high God dwellith not in thingis maad bi hond, as he seith bi the prophete, Heuene is a seete to me, and the erthe is the stool of my feet; what hous schulen ghe bilde to me? seith the Lord; either what place is of my restyng? whethir myn hond made not alle these thingis?"[3]

Contemporary with Wycliffe was Geoffrey Chaucer, who is commonly regarded as the father of English poetry, and who closed his life in the year 1400. Dr Johnson has remarked that "he may, perhaps, with justice, be styled the first of our versifiers who wrote poetically."[4] He was a man of original genius, improved by a familiar acquaintance with writers in several languages. For the native poets who preceded him, he appears to have entertained but little respect: he sought for better models among the Latin, Italian, and French writers, and in all these languages he found works which he either translated or imitated. He possessed a lively fancy, and was a shrewd observer of life and manners. He improved the language, and refined the taste of his contemporaries. He taught them to write, if not with new harmony, at least with new terseness. The work by which he is best known are his Canterbury Tales; and in these he not only exhibits many characteristic delineations of manners, but likewise evinces a rich vein of native humour. They commence with the following verses, which we have selected on account of the elaborate analysis to which they have been subjected by Mr Tyrwhit.[5]

Whanne that April with his shoures sote
The droughte of March hath pierced to the rote,
And bathed every veine in swiche licour,
Of whiche vertue engendred is the flour;
Whan Zephirus eke with his sote brethe
Enspired hath in every holt and hethe
The tendre croppes, and the yonge sonne
Hath in the Ram his halfe cours yronne,
And smale foules maken melodie,
That slepen alle night with open eye,
So priketh hem nature in hir corages;
Than longen folk to gon on pilgrimages,
And palmeres for to seken strange strondes,
To serve halwes couthe in sondry londes;
And specially, from every shires ende
Of Englelond, to Canterbury they wende,
The holy blisful martyr for to seke,
That hem hath holpen whan that they were seke.

In the English language, as it thus appeared in the fourteenth century, the Anglo-Saxon vocabulary was still predominant, but the words had been greatly curtailed in their inflexions. This plan of simplifying the structure of speech is to be traced in other instances, where a rude or a strange race is mingled with a people who have cultivated a more complex language, bearing little or no resemblance to their own. The most essential part of the vocabulary may be acquired without difficulty; but it is not so easy to become acquainted with the inflexions of nouns and verbs, or with some other niceties which belong to language in its more complicated form. Many French words had now been incorporated with the English language; but the compositions of this period began to be marked by an affectation of words derived immediately from the Latin. If Chaucer did not set the example, he at least followed it; and when he aims at a more ornamented style, his use of such phraseology is sufficiently copious. In this respect, he was however exceeded by some of his successors, particularly Hoccleve, Lydgate, and Hawes, who inherited no portion of his strength and originality. Being deficient in taste as well as genius, they devised a verbose and languid style, interspersed with many sonorous and polysyllabic terms, with terms "aureate and mellifluate," which did not assimilate with their native tongue. The same false taste was at length communicated to the Scotish poets. Dr Nott has remarked that Barbour had given his countrymen a fine example of the simple energetic style, which resembled Chaucer's best manner, and wanted little to make it the genuine language of poetry; and that other poets of the same nation, particularly James the First and Henryson, adhered to this model of a simple diction, and affected no other ornament than what the proper use of their language supplied.[1] But ultimately the false taste, which had infected the English poets, was communicated to their brethren of the north.

Gower and Lydgate, whose names are very frequently mentioned with that of Chaucer, are well known to the readers of early English poetry. Thomas Hoccleve, whom his editor supposes to have been born about the year 1370, makes a more inconsiderable figure in the literary annals of that age, but seems nevertheless to claim a passing notice. He was deficient in the essential qualifications of a poet; and, in the opinion of Mr Warton, "his chief merit seems to be, that his writings contributed to propagate and establish those improvements in our language which were now beginning to take place."

The greater part of the fifteenth century was highly unfavourable to the progress of literature in England. The repeated contests for the crown, and the civil wars which they occasioned, were attended with a great waste of human blood, and with that incertainty of possession, and those reverses of fortune, which leave the mind but little relish for such pursuits as are chiefly calculated to gratify the taste. Some individuals, Sir John Fortescue, and a few other writers, have left favourable specimens of prose composition; and they were succeeded by others, who made further improvements in style. Among these we must include Sir Thomas More, Archbishop Cranmer, Sir Thomas Elyot, and Roger Ascham. But from the death of Chaucer, more than a century elapsed before another writer, deserving the name of a poet, appeared in England. This writer was Henry Howard, earl of Surrey, son and heir apparent to the duke of Norfolk, whom however he did not survive. He was beheaded in 1547, in the thirtieth year of his age. Although thus cut off before the full maturity of intellectual vigour, he lived long enough to effect some very material improvements in English poetry. The versification of preceding poets was more properly rhythmical than metrical. Although some improvements had been introduced by Chaucer, he left the number of syllables too indefinite, and did not reach the harmony and compression, of which this noble poet afterwards exhibited an example. One of the changes which he introduced was the use of the heroic blank verse. Langland and other poets had indeed dispensed with rhyme; but their alliterative lines were constructed in a very different manner. In the following sonnet, he bewails the death of another eminent poet, Sir Thomas Wyatt.

Divers thy death do diversely bemoan:
Some, that in presence of thy livelihed
Lurked, whose breasts envy with hate had swoln,
Yield Cæsar's tears upon Pompeius' head.
Some that watched with the murd'rer's knife,
With eager thirst to drink thy guiltless blood,
Whose practice brake by happy end of life,
Weep envious tears to hear thy fame so good.
But I, that knew what harboured in that head,
What virtues rare were tempered in that breast,
Honour the place that such a jewel bred,
And kiss the ground whereas thy corpse doth rest,
With vapoured eyes, from whence such streams avail
As Pyramus did on Thisbe's breast bewail.

Before the close of the sixteenth century, the English language had in a great measure attained that form and structure which it continues to exhibit. A great improvement of taste had been introduced by a more critical and more general study of the ancient classics. William Lilly, the famous grammarian, who had learned Greek at Rhodes, and who had afterwards acquired a polished Latinity at Rome, became the first teacher of Greek at any public school in England. This was at St Paul's school in London, of which he was appointed the first master about the year 1500.[2] The language soon began to be more regularly taught in the universities. At Cambridge the study of it was zealously and successfully recommended by Smith, Cheke, and Ascham, who were themselves distinguished by their proficiency. The elegancies of Latin style began to be better understood, and monkish barbarism was gradually banished. Ascham and Haddon acquired distinction by the style of their Latin prose; and some of the verses of Leland discover a classical vein previously unknown to his countrymen. Before the close of the century, many of the Greek and Latin writers appeared in an English dress, and classical story, with classical mythology, was rendered familiar to the common reader. In addition to the French, the Italian and Spanish languages attracted a great degree of attention; and from all these languages, especially the two former, many works were likewise translated. New sources of knowledge, as well as of fancy, were thus opened, and the English tongue was enriched with a more copious and variegated phraseology. Surrey and Wyatt were succeeded by poets of great genius, by Shakspeare and Spenser, as well as by many others who, though of inferior powers, were yet possessed of a vigorous and brilliant imagination. The prose compositions of Bacon and Raleigh, partaking of the native energy of their authors, exhibited specimens of a condensed and forcible style, to which the preceding age had never attained. During the earlier part of the seventeenth century, ancient learning was assiduously cultivated; and men of great erudition, Selden, Gataker, and others, adorned the literary annals of their country. The prevailing taste of scholars had however a strong tendency to what was scholastic, if not pedantic; and even the poets, such as Donne and Cowley, substituted the subtilties of metaphysical conceits for flights of poetic fancy. Many words, derived immediately from the Latin, were introduced by the learned writers of the period to which we now refer. A considerable number of these has been subsequently rejected, while others are incorporated in the vocabulary. In the mean time, English poetry had nearly reached its highest limits. Milton's Paradise Lost, so eminently distinguished as a work of creative genius, affords the most remarkable illustration of the compass, power, and harmony of the language. Nor is Dryden unworthy of being mentioned with this mighty master of the English lyre. His powers of mind were no doubt different in kind and degree, but he was possessed of a genius truly poetical; and his prose, as well as his verse, exhibits a rich and copious vein of English phraseology.

[1] Nott's Dissertation on the State of English Poetry before the Sixteenth Century (p. cxc.), prefixed to the Works of Surrey and Wyatt. Lond. 1815, 2 vols. 4to.

[2] Warton's Hist. of English Poetry, vol. iii. p. 258.

The subsequent progress of the language our narrow limits will not permit us to trace. The history of the Scotish language is involved in more obscurity. The Celtic tongue is supposed to have been originally spoken in every district of this kingdom; nor has it been found an easy task to account for the introduction of a Gothic dialect, bearing a very close affinity to English. That the Scotish language is merely a dialect of the English, seems indeed to be the more prevalent opinion; and this foreign speech is supposed to have been gradually adopted by the Picts, who are at the same time described as a people of Celtic origin. The ancient history of every race of men which is possessed of no ancient records, and which has not attracted much attention from more enlightened nations, must ever be involved in doubt and incertainty. In the present instance, we have little to guide our enquiries, besides a few scattered and contradictory notices, added to the ordinary and well-ascertained progress of human speech. When other records fail, the history of a nation may sometimes be traced in the history of its language; and a very moderate degree of reflection will enable us to determine the probability of a Celtic people thus unlearning their native tongue, and from deliberate choice adopting another speech completely and radically different.

Dr Geddes, in a Dissertation on the Scoto-Saxon Dialect, has strenuously maintained this extraordinary opinion, which has likewise been adopted by a more recent writer, possessing no portion of his acuteness or learning. "The names," it is stated, "of all the rivers, mountains, towns, villages, and castles, of any note or antiquity, from Berwick-law to Buchanness, and from Buchanness to Arder-Sier, are all evidently Celtic. We must then either suppose that the language of the Picts was a dialect of the Celtic; or that they were not the original inhabitants of the country; or, in fine, that, after the extinction of the Pictish empire, or rather its union with the Irish-Scots, the language of these latter universally prevailed, and effaced the very remembrance of its Gothic predecessor. The second of these suppositions is contrary to history; the third is belied by experience; the first then is the only one that is founded in probability."[1] This observation with respect to the prevalence of Celtic names, though too strongly stated, is not without foundation. We may therefore admit that the south of Scotland was at some remote period inhabited by a Celtic people; but it is not a necessary inference that this people must be identified with the Picts. Whatever hypothesis may be adopted, it is not denied that many Celtic names of places have been retained where the inhabitants have long ceased to speak any dialect of the Celtic language. It may very easily be conjectured that this primitive race of Celts was finally supplanted by new settlers: and that those settlers, whether Scandinavians or some other Gothic tribe, adopted many of the names which the original inhabitants had applied to mountains, rivers, and other conspicuous objects. That a similar process has been followed in innumerable instances, must be obvious to every person acquainted with the history of European settlements in other quarters of the globe: the native appellations are almost always retained to a certain extent, and are mingled with other names, borrowed from the language of the colonists.

If we should suppose the Picts to have been a Celtic people, a very hard problem will remain to be solved:—by what extraordinary means could a distinct race of men, placed in such circumstances, be induced to reject one language, and to adopt another? This radical and unprecedented change Dr Geddes is disposed to ascribe to the operation of such causes as the following; to the temporary subjection of the southern provinces of Scotland by the Northumbrians; to the immense number of captives seized during the ancient wars with the English; to the planting of English garrisons in several of the Scotish towns; to the amicable intercourse of the Picts with the English; and, finally, to the influence of Malcolm Canmore's courtiers, whom he supposes to have learned the English language from Queen Margaret and her retinue. But it may without temerity be affirmed that, in the entire annals of the human race, such an effect was never produced by such causes. In a more refined state of society, the love of knowledge, the hope of gain, or the influence of fashion, may induce many individuals to betake themselves to the acquisition of foreign languages; but the great body of the people will ever be disposed to rest perfectly satisfied with the speech, whether rude or cultivated, which they have derived from their parents. It is only by some great revolution, by a total conquest, or by an overwhelming extent of colonization, that the current language of a country can be materially changed. After the Norman conquest, when French became the language of the court and of the law, and when Norman barons were planted in almost every corner of England, did the combined operation of such causes eradicate the old, and establish a new language in its place? Many new words were unquestionably introduced, but these were merely engrafted on the old stock of the Anglo-Saxon. "Had the Saxon," as Dr Jamieson well observes, "found its way into Scotland in the manner supposed, it would necessarily have been superinduced on the Gaelic. This has always been the case, where one language prevailed over another; unless the people who spoke the original language were either completely or nearly exterminated. Thus was the Norman gradually incorporated with the Saxon, as the Frankish had been with the Latinized Celtic of France. But the number of Gaelic words to be found in what is called Broad Scots bears a very small proportion to the body of the language."[1] And this solitary fact is indeed sufficient to evince that the inhabitants of the south of Scotland cannot be sprung from Celtic ancestors. Dr Geddes has ventured to specify the reign of Malcolm the Third, which commenced in the year 1057, as the period of a general denization of the Saxon tongue in Scotland. "That monarch," he remarks, "had been bred in England, and married an English princess. Her retinue were all English. English, in consequence, would become the language of the court. The courtiers would carry it to their respective homes; their domestics would be ambitious to speak the language of their masters; and thus it would be gradually introduced into every fashionable circle."[2] But to introduce a language into every fashionable circle, is somewhat different from rendering it the current speech of the people: French has long been the court language, and the language of fashionable circles in England, and yet the great body of the people still persist in speaking English.

---

[1] Transactions of the Society of the Antiquaries of Scotland, vol. i. p. 408.

The insuperable difficulty of accounting for such a transition as has thus been supposed, a transition from a Celtic to a Gothic dialect, renders the conclusion obvious and unavoidable, that the Gothic speech of Scotland was derived from a Gothic race of ancestors. Nor is this conclusion altogether free from difficulties, though they are of very inferior weight to those which are to be deposited in the opposite scale. It is the opinion of a late writer, who has investigated the subject with much ability, that the Picts emigrated from Scandinavia;[3] and, according to this opinion, the Picts and Saxons must have spoken two dialects of the same original tongue. The history of these kindred dialects may be illustrated from that of some others, derived from the same Gothic origin. The Islandic, Swedish, and Danish languages are all descended from the ancient Scandinavian. Island, which, as the learned Bishop Müller has remarked, is entitled to particular attention as the foster-mother of northern history,[4] was peopled by a colony of Norwegians in the year 874. This race of men, confined to a remote island, and maintaining but little intercourse, either of peace or war, with other nations, has preserved its ancient language with singular purity.[5] The Swedes and Danes, more extensively engaged in the pursuits of commerce, and more closely connected with the rest of mankind, have exhibited a different progress: but while both languages have receded very widely from the Islandic, they have not receded very widely from each other; a similar state of society, similar relations with other countries, and the study of the same foreign authors, have produced corresponding changes in both. In the history of these two languages, we do not find a complete parallel with that of the Scotish and English: the Swedish and Danish are both dialects of the ancient Scandinavian, while the Scotish is derived from the Scandinavian, and the English from the ancient German. But the Scandinavian and the German proceeded from the same common stock; and when we ascend to a period sufficiently remote, they are only to be regarded as dialects of the same language.

It is not to be concealed that Barbour, Winton, Henry the Minstrel, and other early poets of Scotland, have described their native language as English.[6] This application of the name has been explained, with at least some degree of plausibility, by referring to the circumstance of the Gaelic being then denominated the Scotish language.[7] A Celtic and a Gothic dialect could not well be described by the same term; and "when, by a necessary contingency, the Gothic language had in the same space, though in different nations, retained much the same hues, the name of that dialect, which was spoken by the greater and politer people, was imparted to the other, inhabiting a contiguous part of the very same island."[8] Mr Pinkerton is less fortunate in another suggestion; namely, that it is not more strange to perceive that the Italian, French, and Spanish languages were originally termed Romance. They were all described by this common name, because they were all derived from the language of the Romans; but we are not inclined to believe that the Scotish and the English tongues stand in precisely the same relation to each other. ENGRAVING.

Engraving is the art of cutting metals and precious stones, and representing thereon figures, letters, or whatever device or design the artist chuses.

Engraving being properly a branch of sculpture, is divided into several other branches, according to the matter on which it is employed, and the manner in which it is performed. For the method of

Engraving *on Wood*, see Wood, *Engraving on.*

Engraving on Copper is the making, conformably to some delineated figure or design, such concave lines on a smooth surface of copper, either by cutting or corrosion, as render it capable, when charged properly with any coloured fluid, of imparting by compression, to paper or any similar substance, an exact representation of the figure or design.

Whether we consider the art of engraving, with regard to the utility and pleasure it affords, or the difficulty which attends its execution, we cannot but confess, that on every account it deserves a distinguished rank amongst the polite arts. It is by means of this art that the cabinets of the curious are adorned with the portraits of the greatest men of all ages and all nations. It is by this art also that the paintings of the greatest masters are multiplied, and that the lovers of the polite arts are enabled to enjoy those beauties from which their distant situations seemed to have for ever debarred them; and persons of moderate fortune are thereby enabled to become possessed of all the spirit, and all the poetry, contained in those miracles of art, which seemed to have been reserved for the temples of Italy or the cabinets of princes. When we reflect, moreover, that the engraver, besides the beauties of poetical composition, and the artful ordinance of design, has to express, merely by the means of light and shade, all the various tints of colour and clear obscure,—to give a relief to each figure, and a truth to each object; that he has now to represent a sky serene and bright, and then one loaded with dark clouds,—now the pure tranquil stream, and then the foaming sea tempest-driven; that here he has to express the character of the man, strongly marked in his countenance, and there the minutest ornament of his dress; in a word, that he has to represent all, even the most difficult objects in nature;—we cannot sufficiently admire the vast improvements in this art, and that degree of perfection to which it has at this day arrived. See the article Prints.

Engraving is an art which for the most part is of modern invention, having taken its rise no earlier than the middle of the fourteenth or fifteenth century. The ancients, it is true, practised engraving on precious stones and crystals with very good success; and there are still many of their works remaining, equal to any production of later times. But the art of engraving on plates and blocks of wood, in order to afford prints or impressions, was not known till after the invention of painting in oil.

The different modes of engraving are the following:

1. In strokes cut through a thin wax, called etching ground, laid upon the copper, with a point, and these strokes bitten or corroded into the copper with aquafortis. This is called *etching.*

2. In strokes with the graver alone, unassisted by aquafortis. In this instance, the design is traced with a sharp tool, called a *dry point*, upon the plate; and the strokes are cut or ploughed upon the copper with an instrument of an angular form, distinguished by the name of a *graver.*

3. In strokes first etched and afterwards finished with the graver. By this expedient the two former methods are united.

4. In dots without strokes, which are executed with the point upon the wax or etching ground, bitten in with the aquafortis, and afterwards harmonized with the graver, by means of which instrument small dots are made, or with the graver alone, as in the flesh and finer parts, unassisted with the point.

5. In dots first etched and afterwards harmonized with the dry point, performed by a little hammer; called *opus mallei*, or *the work of the hammer*, as practised by Lutma and others.

6. In mezzotinto, which is performed by a dark barb or ground being raised uniformly upon the plate by means of a toothed tool. The design being traced upon the plate, the light parts are scraped off by instruments for that purpose, in proportion as the effect requires.

7. In aquatinta, a newly-invented method of engraving, in which the outline is first etched, and afterwards a sort of wash laid by the aquafortis upon the plate, resembling drawings in Indian ink, bister, &c. See Aquatinta.

8. On wood, consisting of a single block, on which the design is traced with a pen, and those parts which should be white carefully hollowed out. This block is afterwards printed by the letter-press printers, in the same manner as a book is printed.

9. On wood, consisting of two, three, or more blocks, the first having the outlines cut upon it, the second being reserved for the darker shadows, and the third for the shadows which terminate upon the lights; and these are substituted in their turn, each print receiving an impression from every block. This mode of engraving is called *chiaro-scuro*, and was designed to represent the drawings of the old masters.

10. On wood and on copper. In these the outline is engraved in a bold dark style upon the copper; and two or more blocks of wood are substituted to produce the darker and lighter shadows as before.

Of all those modes of engraving, the most ancient is that on *wood;* or, to speak more properly, the first impressions on paper were taken from carved wooden blocks. From this invention it appears that we are indebted to the brief-malers, or makers of playing-cards, who practised the art in Germany about the beginning of the fifteenth century. From the same source may perhaps be traced the first idea of moveable types, which appeared not many years afterwards; for these brief-malers did not entirely confine themselves to the printing and painting of cards, but produced also subjects of a more devout nature, many of which, taken from holy writ, are still preserved in different libraries in Germany, with the explanatory text facing the figures, and the whole engraved in wood. In this manner they even formed a species of books; such as *Historia sancti Johannis, ejusque Visionis Apocalypticæ*, and *Historia Veteris et Novi Testamenti*, known by the name of *Poor Man's Bible.* These short mementos were printed only on one side; and two of them being pasted together, had the appearance of a single leaf. The earliest date on any of these wooden cuts is 1423, and the subject is *St Christopher carrying the Infant Jesus over the Sea*, preserved in a convent at Buxheim near Menningen. It is of a folio size, illuminated in the same manner as the playing cards; and at the bottom is the inscription, *Christoferi faciem die quacunque tueris. Illa nempe die morte mala non morieris. Millesimo CCCC° XX° tertio.*

Upon the invention of moveable types, that branch of the brief-maler's business, as far as it regarded the making of books, was gradually discontinued; but the art itself of engraving on wood continued in an improving state; and towards the end of the fifteenth and the beginning of the sixteenth century, it became customary for almost every one of the German engravers on copper to engrave on wood also, as may be seen from the first printed books, in which the initial letters were for the most part highly ornamented with various appropriate devices. The works of Albert Durer in this style of engraving are justly held in the highest esteem. Italy, France, and Holland have produced many capital artists of this description; but, for boldness and spirit, the palm must be given to the prints of Christopher Jegher, who worked under the direction of Rubens, and was without doubt assisted by that great master.

The invention of that species of engraving which is distinguished by the appellation of *chiaro-scuro* is also claimed by the Germans, and seems to have been first practised by Mair, one of whose prints of this kind is dated 1499. Many excellent works in chiaro-scuro have also been produced in France; and in Italy it was honoured with the performances of Titian and Parmegiano; but the attempts of Jackson, Kirkall, and others in England, have not been equally successful. Since these times, which may be called the infancy of wood engraving, the art has been carried to very great perfection in Britain; and the present day may boast of higher attainments in this branch than were reached at any former period.

In Germany, about the year 1450, prints from engraved *copper* first made their appearance. The earliest date of a copperplate print indeed is only the year 1461; but however faulty this print may be with respect to the drawing, and however defective in point of taste, the mechanical part of the execution has by no means the appearance of being one of the first productions of the graver. We have also several other engravings, evidently the work of the same master, in which the impressions are so neatly taken from the plates, and the engravings so clearly printed in every part, that according to all appearance they could not be executed in a much better manner at the present day, with all the conveniences which the copperplate printers now possess, and the additional knowledge they must necessarily have acquired in the course of more than three centuries. Hence we may fairly conclude, that if these were not the first specimens of the engraver's workmanship, much less were they the first efforts of the copperplate printer's ability. It is likewise to be observed, that Martin Schoen, who is said, with great appearance of truth, to have worked from 1460 to 1486, was apparently the scholar of Stoltzhirs; for he followed the style of the latter in engraving, and copied from him a set of prints representing the passion of our Saviour. Now, allowing Stoltzhirs to have preceded his disciple only ten years, this carries the era of the art back to 1450, as was stated above. But there is no ground to suppose that it was known to the Italians till at least ten years afterwards. The earliest prints which are known to be theirs are a set of the seven planets, and an almanack by way of frontispiece, on which are directions for finding Easter from the year 1465 to 1517 inclusive; and we may be well assured that the engravings were not antedated, for the almanack of course became less and less valuable every year. In all probability, therefore, these prints must have been executed in the year 1464, which is only four years later than the Italians themselves lay any claim to. The three earliest Italian engravers are, Finiguerra, Boticelli, and Baldini. But if we were to refer these prints to any of the three, we should naturally conclude them to be the work of Finiguerra or Baldini; for they are not equal either in drawing or composition to those ascribed to Boticelli, which we know at least were designed by that artist; and as Baldini is expressly said to have worked from the designs of Boticelli, it appears most probable that they belong to Finiguerra.

With respect to the invention of *etching*, it is not well known to whom it ought to be ascribed. One of the earliest specimens is the print by Albert Durer, known by the name of the *Canon*, dated 1518, and thought by some, with little foundation, to have been worked on a plate of iron. Another etching by the same artist is Moses receiving the Tables of the Law, dated 1524. Etching was also practised in Italy soon after this by Parmegiano, in whose productions we discover the hand of the artist working out a system as it were from his own imagination, and striving to produce the forms which he wanted to express. We see the difficulty he laboured under; and, from the examination of the mechanical part of the execution of his works, we cannot doubt that he had no instruction, and that it was something entirely new to him. If the story be true that he kept an engraver by profession in his house, the novelty of the art is rendered so much the more probable. He died in 1540.

The art of engraving by corrosion, or what is called etching, with aquafortis, must have very early suggested itself to the discoverers of copperplate printing; for it seems to have been the method used by the manufacturers of warlike implements in their decorations of sword-blades and the like: and thus the same artists would soon perceive the facilities afforded by a mode at once easy and expeditious when applied to higher branches, such as the copies of pictures and works of art in general.

As to that species of engraving in which the modes of *etching* and *cutting* with the graver are united, it must have been found necessary immediately upon the invention of etching: it was, however, first carried to perfection by Audran, and is now almost universally practised, whether the work is in strokes or in dots.

Engraving in *dots* is a very old invention, and attributable to the Italians. Agostina de Musis, commonly called *Augustin of Venice*, a pupil of Marco Antonio, used it in several of his earliest works, but confined it to the flesh, as in the undated print of An Old Man seated upon a Bank, with a cottage in the background. He flourished from 1509 to 1536. We also find an example of this method in a print of "A single figure standing, holding a cup and looking upwards," by Giulio Campagnola, who engraved about the year 1516. The background is executed with round dots, made apparently with a dry point; the figure is outlined with a stroke deeply engraved, and finished with dots, in a manner greatly resembling those prints which Demarteau engraved at Paris in imitation of red chalk; and the hair and beard are expressed by strokes. Stephen de Laulne, a native of Germany, followed the steps of Campagnola; and many of his slight works are executed in dots only. Jean Boulanger, a French artist, who flourished in the middle of the last century, and his contemporary Nicholas van Plattenberg, improved greatly on this method, and practised it with much success. It is only, however, of late that it has been considered as an object worthy of general imitation. John Lutma executed this kind of work with a hammer and a small punch or chisel.

The method of engraving in *mezzotinto* was invented about the middle of the seventeenth century; and the invention has generally been attributed to Prince Rupert. See Mezzotinto.

Of the method of engraving in aquatinta an account has already been given under that word. (See Aquatinta.)

But it appears to us not out of place to give the following general directions; and for more particular information the article already mentioned may be consulted.

Engraving in aquatinta was originally invented by Le Prince, a French artist. For a long time, however, his process was kept secret; and his prints, it is said, were at first sold for drawings. As a proof that the art rose at once to perfection, as has already been mentioned, the prints which were executed by him are still admitted to be the finest and best specimens of the art. It appears, however, that he was only acquainted with the powdered grain, and the common method of stopping out. The first who practised this art in England was Mr Paul Sandby. By him, we are informed, it was communicated to Mr Jukes, whose works afford excellent examples of the perfection to which the art has been carried; and although it is now generally practised all over Europe, yet in no country is this done with greater success than in Britain.

The principle of this process consists in corroding the copper in such a manner that an impression from it exhibits the appearance of a tint laid on paper, or a drawing in Indian ink. This is accomplished by covering the copper with some substance which assumes a granulated form, and prevents the acid from acting where the particles adhere; and thus the copper is only partially corroded. The more minute the particles are, it is obvious the impression from the plate will more nearly resemble a wash of Indian ink, or a drawing; but the larger the particles are, the granulation becomes more distinct. The powder or granulation is called the *aquatinta grain*, and is produced in two ways.

The process for using the powdered grain, which was first employed, is the following. The outline being etched on a copper-plate, some substance, which easily melts with heat, adheres to the plate when cold, and resists the action of the aquafortis, is to be finely powdered and sifted. Besides asphaltum, rosin, and gum sandaric, the substances which have been mentioned in the article already referred to, Burgundy pitch, gum copal, gum mastic, as well as some other resins and gum resins, may be employed. Gum copal, it is observed, produces a grain which resists the aquafortis extremely well. Whatever the substance be which is to be employed, the great object of the artist in its application is, to have it equally distributed over the plate. This is an essential part of the operation, and requires considerable attention. The usual method is to tie up a quantity of the powder in a piece of muslin, and to strike it against a stick held at a considerable height above the plate. Thus managed, the powder settles equally over it. The plate being thus covered equally with the dust or powder, the latter is to be fixed upon it by the application of a gentle heat, to melt the particles. This is usually done by holding lighted pieces of paper rolled up, and moving them about till the whole of the powder is melted, which is known by its changing to a brown colour. It is now allowed to cool, and after being examined with a magnifying glass, if the particles appear to be uniformly distributed, the artist proceeds to the next part of the process.

Those parts of the design or drawing to be engraved, which are perfectly white, are to be observed and marked, and the corresponding parts of the plate must be covered or stopped out. This is best done by means of mastic varnish, diluted to such a consistence with turpentine as to work freely with the hair pencil. To give it colour, lampblack should be mixed with it, in order that the touches of the pencil may be distinctly seen. When those parts of the plate which are stopped out are sufficiently dry, a border of wax is raised round the plate, in the same manner as in etching, and the aquafortis, diluted with water, is poured on. This, being the most precarious part of the process, requires the greatest experience. When it is supposed that the aquafortis has remained on the plate for such a length of time that when the impression is taken it will produce the lightest shade in the drawing, it is poured off, and the plate is washed with water and dried. The lightest tints are then stopped out, and the aquafortis is again poured on; and this process is repeated as often as there are tints or shades to be produced in the plate.

Many plates are entirely etched in this way, by alternately stopping out and biting in. It is, however, found to be extremely difficult, and indeed impossible, to produce impressions of minute and complicated objects with the requisite degree of delicacy and freedom. To obviate this difficulty another process has been proposed, by which the touches are laid on the plate with equal ease and expedition as on drawings made with Indian ink. Fine washed whitening is mixed with treacle or sugar, and diluted with water in the pencil, that it may work freely. This is laid on the plate covered with the aquatint ground, in the same way as ink upon the drawing. When this is dry, the whole of the plate is varnished over with a thin turpentine or mastic varnish, and when this is dry the aquafortis is poured on. The varnish immediately breaks up in those parts of the plate where the treacle mixture was laid, and thus they are exposed to the action of the acid, whilst the other parts of the plate remain untouched. Thus the touches or places of the plate where the treacle has been applied are bit in deeper than the rest, and have the precision of touches done with Indian ink. The plate being thus completely bit in, the bordering wax is removed, by gently heating it with a piece of lighted paper. It is then cleared from the ground and varnish by means of oil of turpentine; and being wiped clean with a rag, it is ready for the printer.

But in this method of aquatinting it is found difficult to produce the necessary degree of coarseness or fineness in the grain; and plates which are engraved in this manner afford but a small number of impressions before they are worn out. On this account it is now more rarely followed.

The other method of producing the aquatint ground, which is most generally adopted, is the following. A resinous substance, as common resin, Burgundy pitch, or mastic, is dissolved in spirits of wine. This solution is poured all over the plate, which is inclined, till the whole of the superfluous fluid is drained off, and what adheres to the plate becomes quite dry in a few minutes. The plate being then examined with a magnifying glass, it will appear that the whole of the spirit having evaporated, the resinous matter is left in a granulated state, or is cracked in every direction, and adheres strongly to the copper. In this way a regular and beautiful grain is easily produced, which will be found preferable, at least for most purposes, to that which is produced by the former method. The grain being thus formed, the other parts of the process are conducted in the same manner as before described.

Such are the usual methods of conducting this process. We shall add a few hints which may be found useful respecting the different parts of it. With regard to the materials which are employed, it is to be observed that the spirits of wine should be rectified, and of the very best quality. Resinous matters, as common resin, Burgundy pitch, and gum mastic, yield grains of a different appearance and form; so that advantage may be taken of this circumstance by using them sometimes separately, and sometimes mixed in different proportions, according to the views and taste of the artist. Different proportions of resin may be employed to produce grains of different kinds. When a coarse grain is intended, a greater proportion is to be employed; and when a fine grain is wanted, a smaller proportion of resin only is required. The proper proportions may be ascertained by providing a number of spare pieces of copper; on these the liquid may be poured, and the grain examined, before it is applied to the plate which is to be engraved. After the solution is made, it should remain undisturbed for a day or two, till the impurities of the resin have subsided, and the liquid becomes quite limpid. This is the best method of freeing it from impurities; for if it be strained through linen or muslin, it is mixed with hairs, which are extremely injurious to the grain. It may be added, that the apartment in which the fluid is poured on the plate should be perfectly still, and entirely free from dust; for if any fall on the plate while it is wet, the grain forms a white spot, which cannot be removed. Great care should be observed in cleaning the plate before the ground is laid on. This is done with a bit of rag and whitening. The smallest stain or particle of grease produces a streak or blemish in the grain. Still, however, with all the attention which can be employed, and with the utmost delicacy in the management, it is necessary to observe that the process is extremely precarious and uncertain; and even the most experienced artists find themselves frequently subject to very unaccountable accidents.

Artists have frequently complained of the inconvenience arising from the fumes which proceed from the action of the acid upon the copper when the plate is large. To remedy this inconvenience, the following arrangement, which seems well calculated to answer the purpose, was suggested by Mr Cornelius Varley, an artist who distinguished himself no less by his mechanical abilities than by the exquisite productions of his pencil in water colours: "Get a frame made of common deal, or any kind of wood, three or four inches deep, covered with a plate of glass, and open at one side; and let the side opposite to this have a round opening, communicating by means of a common iron pipe with the ash-pit of any little stove or other fire-place, shut up from all other access of air but what must pass through the pipe. It is obvious that any fumes rising from a copper-plate laid under such a frame will be carried backward into the iron pipe by the current of air required to maintain combustion in the stove, and will by this means be carried up the chimney, in place of being allowed to fly about in the apartment. The pipe may be very conveniently used by carrying it down through the table to the floor, and so along to the place where the chimney may chance to stand; and when the frame is not wanted, the pipe at one of the joinings may be made to answer the purpose of a hinge, by which to turn up the frame against the wall, where it may be secured, while out of use, by a button or any other contrivance."[1]

This method of engraving in aquatinta seems to be chiefly adapted for slight subjects in general, and for imitations of sketches and washed drawings. But for the production of prints from finished pictures it is by no means calculated, because it is not susceptible of that accuracy in the nice management of the tints which is necessary for this purpose. It is equally unsuitable for book plates, because, without retouching the plates, the number of impressions which can be thrown off is very small. On these accounts, therefore, it is to be considered as greatly inferior to the other modes of engraving. But as it is more expeditious, and may be attained with greater facility, it is undoubtedly useful when it is confined to those subjects for which it is peculiarly calculated. This rapidity of execution, however, and facility in acquiring the practice of the art, are followed with the unfortunate circumstance, that they favour the production of an indiscriminate multitude of prints, which, it is to be feared, may rather tend to vitiate than improve the public taste.

Engraving with the tool was the kind originally practised, and it is yet retained for many purposes. For though the manœuvre of etching be more easy, and other advantages attend it, yet where great regularity and exactness of the stroke or lines are required, the working with the graver is much more effectual; on which account it is more suitable to the precision necessary in the execution of portraits, as there every thing the most minute must be made out and expressed, according to the original subject, without any license to the fancy of the designer in deviating from it, or varying the effect either by that masterly negligence and simplicity in some parts, or those bold sallies of the imagination and hand in others, which give spirit and force to history painting.

The principal instruments used in engraving with the tool are, gravers, scrapers, a burnisher, an oil-stone, and a cushion for bearing the plates.

Gravers are made in several forms with respect to the points, some being square, others lozenge; the square graver being designed for cutting broad and deep, and the lozenge for more delicate and fine strokes and hatches. The most generally useful are those of a form between the square and lozenge; and they should be of a good length, small towards the point, but stronger upwards, that they may have strength enough to bear any stress which there may be occasion to lay upon them; for if they be too small and mounted high, they will bend, which frequently causes their breaking, especially if they be not employed for very small subjects.

The burnisher is used to assist in the engraving on some occasions, as well as to polish the plates. It is made of fine steel well polished. The burnisher is sometimes formed at one end, and a scraper on the other, each about an inch and a half long from the point; between them about four inches of the instrument is made round, and serves as a handle, and is thicker in the middle than at the necks, where the burnisher and scraper begin, which necks are only a quarter of an inch in diameter. The principal application of the burnisher in engraving, besides its use in polishing the plates, is to tone and harmonise the work, and to take out any scratches or accidental defacings that may happen to the plates during the engraving; or to lessen the effect of any parts that may be too strongly marked in the work, and require to be taken down.

A cushion, as it is called, is likewise sometimes used for supporting the plate in such a manner that it may be turned every way with ease. It is a bag of leather filled with sand, and should be of the size which will best suit the plates it is intended to bear. Cushions are round, and about nine inches over, and three inches in thickness.

The cushion, made as above directed, being laid on the table, the plate must be put upon it; and the graver being held in the hand in a proper manner, the point must be applied to the plate, and moved in the proper direction for producing the figures of the lines intended; observing, in forming lines, to hold the plate steady on the cushion, and where they are to be finer, to press more lightly, using greater force where they are to be broader and deeper. In making circular or other curve lines, hold your hand and graver steadily; and as you work, turn your plate upon the cushion against your graver, otherwise it will be impossible for you to make any circular or curved line with that neatness and command of hand which by this means may be acquired. After part of the work is engraved, it is necessary to scrape it with the scraper or graver, passed in the most level direction over the plate, to take off the barb or roughness formed by the cutting of the graver; but great care must be taken not to incline the edge of the scraper or tool in such a manner that it may take the least hold of the copper, as it would otherwise produce scratches in the engraving; and, that the engraved work may be rendered more visible, it may afterwards be rubbed over with a roll of felt dipped in oil. In using the graver it is necessary to carry it as level as possible with the surface of the plate; for otherwise, if the fingers slip betwixt them, the line that will be produced, whether curved or straight, will become deeper and deeper in the progress of its formation, which entirely prevents strokes being made at one cut that will be fine at their extremities and larger in the middle, and occasions the necessity of retouching, to bring them to that state. For this reason it is very necessary for those who would learn to engrave in perfection, to endeavour, by frequent trials, to acquire the habit of making such strokes, both straight and curved, by lightening or sinking the graver with the hand, according to the particular occasion. If, after finishing the design, any scratches appear, or any part of the engraving be falsely executed, such scratches or faulty parts must be taken out by the burnisher, and further polished, if necessary, by the above-mentioned roll.

---

[1] *Philosophical Magazine*, vol. xxiii. p. 137.

The dry point, or needle, which has been of late much used in engraving, is a tool like an etching point, which being drawn hard on the copper, cuts a stroke and raises a burr; the burr is scraped off, and there remains a stroke more soft and delicate than can be produced in any other way.

Although the instruments for the use of the engraver above enumerated and described are very simple, yet we have thought it advisable to subjoin the following figures illustrative of their forms, and about half the dimensions of those employed.

Fig. 1.
Graver.

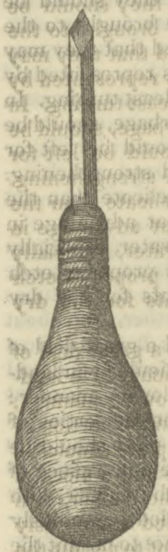

Fig. 2.
Dry Point, or Etching Needle.

Fig. 3.
Scraper.

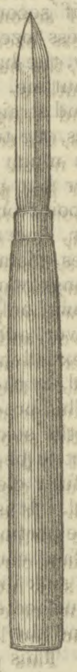

Fig. 4.
Burnisher.

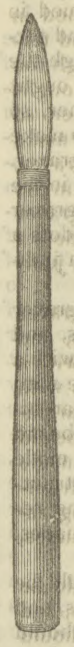

Fig. 5.
Ball of Etching Ground, covered with silk.

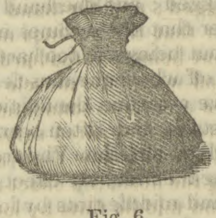

Fig. 6.
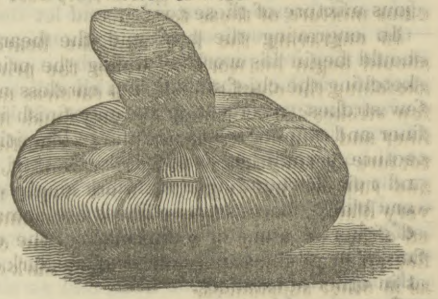
Dabber, covered with silk, and stuffed with cotton or wool.



The plate is covered with etching ground in the following manner: Heat it upon a stove or otherwise till it melt the ground in the silk bag, fig. 5, which must be spread equally over the surface of the copper by means of the dabber, fig. 6. The ground is then to be moderately smoked all over with a candle, and when the plate is cold it is ready for use.

Etching ground is composed of virgin wax and asphaltum each two ounces, and of black and Burgundy pitch each half an ounce. Melt the wax and pitch in a new-glazed earthen pot, and add to them by degrees the asphaltum finely powdered; boil the whole until such time as, by taking a drop upon a plate, it will break when it is cold, on bending it double three or four times between the fingers. The ground, being sufficiently boiled, must be taken off the fire, and, being allowed to cool a little, must be poured into warm water if the weather be cold, or cold water if the contrary, in order that it may be the more easily worked with the hands; for it should be pulled a long time, to mix the ingredients more completely, when it may be divided into small balls for use. The fire must be moderate, for fear of burning the ground; and the ingredients must be stirred during the whole time of preparation, particularly when the asphaltum is being put in.

Wax for surrounding the plate in the process of biting in with aquafortis is made of one pound of Burgundy pitch or black pitch, and of bees' wax half a pound, melted over a slow fire. When melted, add about a gill of sweet oil, and when moderately hot, pour the whole into water, pull it well, and fashion it into balls for use.

In the conduct of the graver and dry point consists the whole art, for which there are no rules to be given, all depending on the habitude, disposition, and genius of the artist. However, besides the explanations already given, some general observations and directions may not be improper. As the principles of engraving are the same with those of painting, a person cannot expect to attain any considerable degree of perfection in this art who is not a good master of design; and therefore he ought to be well acquainted with both perspective and drawing in general; for, by the proper degradations of strong and faint colours, he will be enabled to throw backwards the figures and other objects of the picture or design which he proposes to imitate, and which the painter often intrusts to the discretion of the engraver. In working, the strokes of the graver should never be crossed too much in a lozenge manner, particularly in the representation of flesh, because sharp angles produce the unpleasing effect of lattice-work, and take from the eye the repose which is agreeable to it in all kinds of picturesque designs; we should except the case of clouds, tempests, waves of the sea, the skins of hairy animals, or the leaves of trees, where this method of crossing may be admitted. But in avoiding the lozenge, it is not proper to get entirely into the square, which would give the work too much of the hardness of stone. In conducting the strokes, the action of the figures and of all their parts should be considered; it should be observed how they advance towards or recede from the eye; and the graver should be guided according to the risings or cavities of the muscles or folds, making the strokes wider and fainter in the light, and closer and firmer in the shades. Thus the figures will not appear jagged; and the hand should be lightened in such a manner that the outlines may be formed and terminated without being cut too hard. However, though the strokes break off where the muscle begins, yet they ought always to have a certain connection with each other, so that the first stroke may often serve by its return to make the second, which will show the freedom of the engraver.

In engraving the flesh, the effect may be produced in the lighter parts and middle tints by long peeks of the graver rather than by light lines, or by round dots, or by dots a little lengthened by the graver, or, best of all, by a judicious mixture of these together.

In engraving the hair and the beard, the engraver should begin his work by laying the principal lines, and sketching the chief shades, in a careless manner, or with a few strokes; after which he may finish it at leisure with finer and thinner strokes to the extremities. When architecture or sculpture is to be represented, except it be old and ruinous buildings, the work ought not to be made very black; because, as edifices are commonly constructed either of stone or white marble, the colour, being reflected on all sides, does not produce dark or brown shades, as in other substances.

In engraving cloths of different kinds, linen should be done with finer and closer lines than any other sorts, and be executed with single strokes. Woollen cloth should be engraved wide, in proportion to the coarseness or fineness of the stuff, and with only two strokes; and when the strokes are crossed, the second should be smaller than the first, and the third than the second. Shining stuffs, which are generally of silk or satin, and which produce flat or broken folds, should be engraved more hard and more straight than others, with one or two strokes, as their colours are bright or brown; and between the first strokes other smaller ones may be interlined. Velvet and plush are expressed in the same manner, and should always be interlined. Metals, as armour, &c. are also represented by interlining, or by clear single strokes. In architecture the strokes which form the rounding object should tend to the point of sight; and when whole columns occur, it is proper to produce the effect as much as possible by perpendicular strokes. If a cross stroke is put, it should be at right angles, and wider and thinner than the first stroke. In engraving mountains, the strokes ought to be frequently discontinued and broken for sharp and craggy objects; they should be straight, in the lozenge manner, and accompanied with long points or dots; and rocks should be represented by cross strokes more square and even. Objects which are distant towards the horizon should be kept very tender. Waters that are calm and still are best represented by strokes which are straight and parallel to the horizon, interlined with those that are finer, omitting such places as, in consequence of gleams of light, exhibit the shining appearance of water; and the form of objects reflected from the water at a small distance upon it, or upon the banks of the water, are expressed by the same strokes, retouched more strongly or faintly as occasion may require, and even by some that are perpendicular. For agitated waters, as the waves of the sea, the first strokes should follow the figure of the waves, and may be interlined, and the cross strokes, if any, ought to be very lozenge. In cascades the strokes should follow the fall, and may be interlined. In engraving clouds, the lines should sport, when they appear thick and agitated, in turning every way, according to their form and agitation. If the clouds are dark, so that two strokes are necessary, they should be crossed more lozenge than the figures, and the second strokes should be rather wider than the first. The flat clouds which are lost insensibly in the clear sky should be made by strokes parallel to the horizon, and a little waving; if second strokes are required, they should be more or less lozenge; and when they are brought to the extremity, the hand should be so lightened that they may form no outline. The flat and clear sky is represented by parallel and straight strokes, without the least turning. In landscapes, the trees, rocks, earth, and herbage, should be etched as much as possible; nothing should be left for the graver but perfecting, softening, and strengthening. The dry point produces an effect more delicate than the graver can, and may be used to very great advantage in linen, skies, distances, ice, and often in water, especially in small engravings. In most things it is proper to etch the shadows, only leaving the lighter tints for the dry point, graver, and other instruments.

Much excellence may be attained, and a great deal of time saved, by the process of rebiting, particularly in landscape. This process is effected in the following manner: When all the strokes have been laid in upon the portion of any subject to be rebit, the lines upon the plate should be very carefully cleaned out with turpentine and a piece of stale bread. It is then to be heated, and the dabber, with a moderate portion of etching ground, applied dexterously to the surface, care being taken, however, not to permit the ground to sink into the lines, but only to cover the intermediate surface effectually. The aquafortis is now to be applied, and the lines bit down or corroded to the depth required. This process is, comparatively speaking, of recent invention, and was wont to be esteemed precarious and difficult in the management; but a little experience, and the great demand for illustrated works of late years, have been the means of rendering this, as well as other matters of detail in the engraver's art, much more certain.

To imitate *chalk drawings*, a mixture of varied and irregular dots are used, made more or less soft, so as to resemble the grain produced by the chalks on paper. Every stroke of the chalks on paper may be considered as an infinite number of adjoining points, which are the small eminences of the grain of the paper touched by the chalk in passing over it. When the copper-plate has been properly prepared with etching ground, as in the common method of engraving, the drawing to be imitated may be counterproved on the ground of the plate. If this cannot be conveniently done, black-lead pencil or red chalk must be applied to varnished or oiled paper, and this chalk or pencil transmitted to the ground. The outlines of the object must be formed in the etching by points, whose magnitude and distance must be determined by the quality of the strokes in the original drawing. The artist may be provided with pointed instruments or needles of various sizes, with single or double points. In forming the light and shade, he should distinguish between those hatches which serve to express the perspective of the object, and those which form the ground of it. The principal hatches should be more strongly marked; the middle tints, if etched, should be marked lightly, or they may be left till the varnish is taken off, and be perfected with a greater degree of softness by needles, or the point of the graver, as the original may require. There is nothing peculiar in the method of applying the aquafortis in this kind of engraving; but it may be observed that it should not be left so long as to corrode too much the lighter parts. If the light parts are sufficiently corroded, they may be stopped up with turpentine varnish and lampblack mixed together, and the aquafortis may be applied again to the stronger parts; for it will be no detriment to them, if the points which compose the shade burst into one another, provided the extreme be avoided. When the work of the aquafortis is finished, and the varnish taken off the copper, it will be necessary in the softest parts, such as the flesh, to interstipple with proper points, as an effect will be thus produced more delicate than it is possible to attain with the aquafortis only; and the strongest shades will require additional strength to be given them with small strokes of the graver. Drawings made with chalks of different colours may be imitated in this manner, if a plate be provided for every colour. This method of engraving is intended to form a kind of deception, so that the connoisseur may not be able, on the first inspection, to distinguish between the original drawing and the engraving made in imitation of it; and it is extremely useful, as it serves to multiply copies of drawings left by those masters who excelled in the use of chalks, and thus to form and improve young artists, who could not have access to the originals in the practice of drawing.

To this account of the history and practice of the art of engraving we shall annex the following ingenious observations by an eminent artist.[1] We present them to our readers without alteration or abridgment.

On the linear art in general.

"When compared with painting, the art of engraving is but a recent invention, being coeval only with that of printing; and, like that noble art, it possesses not only a similar, but a greater power of multiplying and extending the productions of genius over the world, for its language is universally understood.

"It would have been well for the art if it could boast of a more remote date, as we might then have had many more of the finest designs of the first painters of antiquity, now doomed to oblivion, saved from the rude ravages of time.

"But this invention seemed to be reserved for the fourteenth century, and its improvements for the age of Louis XIV.; an age in which a number of artists, who may be said to have invigorated the art and invested it with beauty, arose both in France and Italy.

"Lines, in the first state of the art, like every other pursuit whose excellence is progressive, were comparatively rude and unmeaning, and had nothing more to recommend them than merely representing a particular sort of markings, or slight hatchings with the pen, without any other apparent degree of execution or expression; although it is our pride to acknowledge that it has been not a little beholden to the elegant etchings of the great masters in painting, as well as to their drawings in pen and ink in its early stages, by which means an eminent degree of taste was introduced into the art, particularly in the department of linear disposition; amongst those, the drawing of a Raffaelle, Michel Angelo, and the learned Da Vinci, some of which we have occasionally seen and admired. Some by Da Vinci were hatched in a square but delicate manner, with a white fluid, on dark-coloured paper. Those of Michel Angelo and Raffaelle inclined more to the lozenge, in black or brown ink. They even carried this style of hatching with the pencil into their pictures, some of which adorn the Vatican; and in the famous cartoons in his majesty's collection by Raffaelle. Baccio Bandinelli generally hatched his lines in one direction, particularly a Taking down from the Cross, which was sold in London at the sale of the late Sir Joshua Reynolds' drawings. Vicenzio Dante hatched in a similar way about the year 1550. Julio Romano used also to draw in this style with the pen, several of which are still to be found in the most select cabinets of men of taste; and for near a century and a half after the invention of etching, it is rare to mention a painter of eminence who was distinguished in drawings, who did not annex this art to that of painting. But with the application of the burin the art has been gradually improving till the present period. Linear[2] engraving is nothing more than drawing elegantly on copper. It became more studied as it was found capable of representing the various appearances of nature. The texture or surface of objects became proportionally discriminated by such peculiar modifications of the line as seemed most suitable to the subject represented, although, at the same time, it rendered it much more arduous in the execution. Hence arose that diversity of style, and that scope for succeeding excellence, which, by combining elegance with simplicity and beauty, distinguished those artists who have been most conspicuous in its improvement.

"It has been said that we are indebted for the origin of this art to an ingenious Florentine, Masso Finiguerra the sculptor. He was succeeded by a number of other ingenious men, among whom we rank Botticelli, Andrea Mantigna, and other able designers; and in Germany, Albert Durer, Aldgrave, and Lucas van Leyden, who severally contributed their labours. But in the fifteenth century the works of the divine Raffaelle began to be multiplied by the correct graver of Marco Antonio, an artist whose prints were the delight of that great painter. Antonio had many imitators, but none who equalled him for justness of contour, for which his works will be ever highly appreciated among the early productions of the art. Having had occasion to mention a few of the principal artists who reared the scaffolding of this elegant art, we shall proceed to those who have so much distinguished themselves in finishing the superstructure. Among those, Augustino of Venice began to introduce a better disposition of line in his shades, as well as the ingenious Bolognese, Augustino Caracci; whilst Egedius Sadelaer displayed no less zeal in Germany. In the sixteenth century the art displayed still more vigour and taste, and seemed to have but little more wanting; for all that meagre dryness of line began to disappear, which so manifestly marks the early works of Il Tedesco, Aldegraff, and other artists of a former period. Their works became consequently more rich in style, by embracing the best productions of the pencil; and as they were applied to a greater number of ideas, they became still more interesting and successful.

---

[1] Francis Legat, Esq. historical engraver to George IV. when Prince of Wales, and F. A. S. E.

[2] The author has taken the liberty of adopting here the word *linear*, from its strict analogy to this mode of engraving, and with the approbation of some of the first professors, both in painting and engraving.

"Patrons were numerous and liberal; and it is but proper to remark, that the various artists, on their part actuated by a becoming zeal which was highly creditable to themselves, were indefatigable. This is a circumstance not less worthy of imitation than the many admirable monuments of the art which they produced. Few but admired the works of Masson, Poilly, Nantueil, and Rousselet; and some time after the death of the ingenious Cornelius Bloemart, who had given a grace to his lines hitherto unknown at Rome, the matchless Audran and Edelinck displayed their excellent productions at Paris. But arts are liable to fluctuate; and when the art of engraving began to decline abroad, it gradually displayed a high degree of lustre in our own country; and the variety of styles which has since sprung from the original manner of engraving, shall be the subject of the following sketch.

"We shall, therefore, treat more particularly of the disposition of the lines, and their consequent effects, distinguished by the terms *linear expression*, *imitation*, *disposition*, and *harmony*; with a strict investigation of the first and most approved subjects, either in etching or engraving, and of their essential beauties, as far as they may tend to illustrate the subject.

"As the great object of this mode of engraving is to adopt those lines the most expressive of the form and character of whatever happens to be represented, it is necessary to begin by maturely investigating not only the action, but the cause and correspondent effects, of the original picture, in order that the artist may avail himself of all that is most beautiful in his translation, and efficient in the aggregate, either with respect to the expression, spirit, or sentiment.

n linear xpression ad dispo- tion,

"When historical subjects consist of several figures where there is generally a variety of draperies, some of them appearing thick and cumbersome, others more thin and flexible, sitting close and elegant on the limbs, being composed of a finer texture or thread; the coarser stuffs are consequently more effectually represented by a bolder line, as the thinner sort, by the application of a fine line, gives a more lively representation; a discrimination which has been observed of late by the most approved modern artists in linear engraving. Observations of this description, when treated in a liberal manner, not only superadd a degree of truth, but even render the subjects sweeter to the eye of fancy. In the early stages of the art some excellent artists have been led into particular and limited systems. In the works of such as have affected to describe every subject in the same line indiscriminately, even the arms of the most delicate women are often engraven as if perfectly polished, by approaching to a metallic appearance, a mode not uncommon among the second or third class of artists about the beginning of the last century; by which manner all that softness and delicacy was neglected which is so happily effected in the linear productions of Strange, Bartolozzi, Morgan, Sharp, Heath, and others. Those who are acquainted with the works of the ingenious Chaffard, must with pleasure have perceived in his foliage how even the texture of flowers is imitated from the delicate line-like fibres of which they are composed, issuing from the stem and spreading their silken beauties to the sun; and in this class of imitation, the clear transparency of glass, the rough texture of woollen, the thinness of lawn, the flickerings of satin, or the lightnings of steel, as well as the rude rock, the lucid lake, or the flashing of the torrent, are all admirably adapted to linear effect by the almost infinite diversity in their construction and general constituent principles, strictly observing on what laws the beauty of lines consists, by ever keeping in view the due balance of taste, and a noble simplicity of style throughout. It is the business of the skilful artist to overpower and subdue the difficulties in his profession; for no excellence in art is of cheap or vulgar acquisition. Let it be remembered, that with forming steel even the enchanting graces of the Venus de' Medicis were hewn from a rock, and the almost breathing Apollo from a block of Parian stone.

"An elegant English poet, in a critical essay on poetry, observes that the sound should seem an echo to the sense; so should the lines in a fine print seem to harmonize with the subject, by flowing with the external cast of the features, and the predominant passion expressed in the original picture; for the same character and disposition of the lines that suit the action of the muscles in one passion, will be found to appear more vacant and less expressive when applied to others, however graceful they may appear.

"As this is a point of view to which the art has never yet been fully extended, perhaps it may meet with some degree of attention, as it will be found of utility in forming a principle respecting disposition, more particularly in historical subjects, where the passions are required to be nicely expressed; and although it may admit of some slight exceptions, it is a principle that will in general be found to be true.

"For example, let it be supposed that the passion of the figure represented is that of joy, the lines should seem to expand and swell, with every acting muscle, in the most delicate manner possible.

"But, on the contrary, if the subject displays deep sorrow, they should rather incline downward, partaking somewhat of the half straight, seeming to act apparently in perfect unison and conformity with the features of the face, with all due subordination to the general effect of light and shadow.

"Various observations may be made in this manner on the principal passions expressed in the human countenance, which are but few comparatively, even from the slightest movement to the boldest action. We often find, on examining the works of those masters who are not so conspicuous for great clearness of execution, that they have been occupied by the disposition and energy of the lines, as in the magnificent and masterly prints of the battles of Alexander, from the pictures of Charles le Brun, engraved by Gerrard Audran, where the executive department is no less conspicuous from the burin of the Chevalier Edelinck in the fine print of the tent of Darius; whilst Audran displays the true spirit of art, but rarely avails himself of much of the mechanical principles. The field and tumult of battle seemed admirably calculated to call forth his rapid powers, particularly in works of magnitude.

"The less active scenery of the tent of Darius was well adapted to the splendid talents of Edelinck, who was admirably qualified to display subjects of this nature. This is sufficiently obvious from the beautiful and interesting group of the queen mother, and her illustrious family, kneeling at the feet of the conqueror; his impressive print of the Magdalene, or his most admirable portraits of the dignified clergy, distinguished authors, and eminent artists. These, in point of engraving, are no less remarkable for taste in the execution, than for truth and nature in expression.

"In one of the battles of Alexander, the group where Porus is wounded and supported by the soldiers, the rough discrimination of line finely accords with that bold deportment of character in the grim visage of that gigantic prince, whilst a more delicate line marks the youthful countenance of Alexander; a discrimination which is totally lost in the large Dutch copy by De Vos.

"In the same print the figures of Alexander and Clytus are finely relieved from the distant scenery by the varied description of engraving on their armour, drapery, and horses. The latter are managed with such freedom and spirit, that it is difficult to say whether the horses or figures teem the most with masterly execution; particularly the white war-horse on the right extremity of the print.[1]

"Had Audran superadded a still greater portion of the delicacy and clearness of handling so conspicuous in Edelinck and other eminent artists since that period, it would undoubtedly have given an additional beauty to his other transcendent acquisitions; namely, the vast spirit of his lines, and power in drawing.

"But it is seldom the lot of an individual to combine every excellence. Arts too have their infancy, for they generally require the labour of ages to bring them to maturity and perfection; and it yet remained to unite and ameliorate the polish of Edelinck, to the spirited style of Audran. Without prejudice or partiality, a considerable degree of this excellence will be found in the best works of British art, as we shall hereafter exemplify.

"Another fine specimen of linear engraving, and of a different class, is the celebrated storm of Balechow, from a picture of the famous Vernet. In this print he has transmitted with the graver a certain fluidity and action in representing the liquid element, to which the art had never before attained. To a grandeur of style in the bold swelling of the waves he has superadded the utmost transparency of line; at the same time having attended to all that light restless spray which seems sporting to the gales as they roll along. In a fanciful mood one might almost imagine they heard the motion of the water; so finely did this discriminating artist translate this admirable picture.

"When we consider the period in which this distinguished work was engraved, and that little or nothing had been previously done in that department of a similar excellence, it is hoped it will be a sufficient apology for the degree of admiration here expressed; for, as Lord Verulam truly observes, "we are too prone to pass those ladders by which the arts are reared, and generally reflect all the merit to the last new performer." We have already observed, they are seldom reared with rapidity, and oftentimes that which is considered an invention is only a long succession of trials and experiments, which have gradually followed each other, and ought rather to be considered as a series of human mind than the knowledge of an individual, being the works of ages. In any point of view, the present subject will ever be considered as a high improvement and an elegant acquisition in the annals of the linear art. But in historical subjects this artist is by no means equal in point of taste or discrimination. His print of St Genevive undoubtedly ranks high in the first classes of engraving. Had his taste in other respects been equal to his powerful clearness of execution, it would have been almost unparalleled; but it betrays a want of that essential, even in his mode of thinking. Patience and labour are everywhere too prevalent. It remained for Woollet to excel both in figures and landscapes.

"In the various styles and modifications of this expressive art, from the neat to the feeble, and from the bold to the extravagant, taste stands sole arbitress; in brief, it is she who distributes variety with spirit, and conceals the appearance of intricacy and labour; who, by a due modification of line, unites clearness to softness, arresting the hand of the skilful artist from every effort inconsistent with her powers; producing at once to the mind all that agreeable finished combination or harmony which ever accompanies and constitutes the perfection of true art.

"In the execution of subjects of imagination, there is a perpetual scope for calling forth the fancy of the engraver, as the various combinations of lines are inexhaustible, uncommon effects, such as aerial spirits, or celestial beings blended with the light, or ghosts commingled with the gloom, or fairy elves by moonlight, who trip the sands, and yet no footing seen; or wood nymphs laving their taper limbs in the limpid element. Such subjects, in point of style, depend entirely upon the beauty, lightness, and transparency of execution; for those that are merely ornamental or grotesque demand a style of a different cast from that of the serious or historical, as they require a less degree of truth even from the burin. In these cases the style may be as capricious as the subjects. Those of Raffaelle, in the Vatican, display an uncommon degree of taste, and particularly in the elegant flow of line with which they are composed.

"In all works of taste and genius, those which may appear the most simple at a transient glance, will be often found to contain the most art on a more mature investigation. The first impression may strike the fancy, but the second generally calls up the discriminating powers of the judgment.

"Arts generally rise in our esteem according to the degree of exertion of the mental powers which they require; and, as lines are capable of various styles, those which are most congenial to the subject represented ought to be adhered to in preference to every other consideration. Teniers and Gerrard Douw demand all the fidelity and delicacy of the burin in describing the various draperies and individualities which belong to that class of painting; but, in proportion as the contour is composed of fewer parts, and the forms more full and elegant, the beautiful flowing qualities of the graver are increased, and its lines glide more gracefully over the figures, as may be found in the works of Strange and others, from Guido and Correggio. This distinction will not appear so obvious on a superficial view of the art. But, on a due investigation, it will be found, that not only a different modification of lines is necessary to the various classes of painting, but that even a different description of style is requisite to characterize some of the masters in each particular class, from the sublime and elevated figures of a Raffaelle and Michel Angelo, to the simple cottagers of Adrian Ostade.

"When we take a more comprehensive view of the art, we often find, that the styles which are adopted in the different countries in Europe by the artists where the art has in any degree been cultivated, are generally regulated by the modes of painting, drawing, and even the colouring respectively in each, whether historical, portrait, or landscape, and is proportionably appreciated according to the effective beauty and elegance of the execution.

"It is not improbable that the clear mode, which at present constitutes the modern German school, is a refinement on the simple style of Cornelius Bloemart.

"In Italy, Jachimo Frey, that astonishing Swiss, from his masterly expertness in drawing, and a rapid use of the etching steel and the nitre, almost produced an entire revolution in the art. The unprecedented richness and ease, the freedom and energy of his style, and the number and magnitude of his works, attracted all Italy, and tended

---

[1] Whenever M. Bartolozzi happened to speak of those prints, he always expressed himself with a great degree of enthusiasm, thinking himself extremely fortunate in having works of such excellence in his possession.

greatly to improve the Roman school. About the year 1672 we find him working jointly with the nervous Dorigny Frezza, and Vanauden Aird. From this source we can perceive the style of Wagner, of Cars in France, and various masters now living; namely, Francisco Bartolozzi, Giovanni Volpato, Dominico Cunigo, and some of the early works of the excellent Raphael Morghen.

"In many instances Frey indicates, that if he had considered it of sufficient consequence to the art, he could have engraved with more clearness, particularly by his curious copy, from the celebrated print by Edelinck, of the Madona and Child, with St John and Angels, from Raffaelle; and, although but an imitation of another style, tends to show the versatility of his talents, when the judgment is for a while suspended to know which is the original. We find a performance of Frey's, entitled *La Charité Humaine*, dated 1723; a print was afterwards engraved from the same subject at Paris by Daulle, dated 1763, in which he has rather been too profuse in the more mechanical part of the art, and destitute of that ardour which a well engraved work should not only inspire, but maintain.

"It is not enough for lines to be only well disposed, but also full of expression; neither is it enough for a line to be only clearly cut, but it must also be free; for in a certain free light spirited lines convey an idea of animation, and are suited to subjects of that description; while the long, sweeping, and bold lines are better adapted to the solemn and majestic productions of the pencil.

"A fine print, like a miniature picture, ought to be viewed near the eye; as in itself, from the nature of the art, will be found a due subordination of effect, ever receding, from the bold and articulated lines in the fore ground, to those which are more evanescent and remote.

"The graceful birch, the mountain ash, and the oak, have each their peculiar bark and texture; and these, when freely indicated, stamp their mark and character most completely to the eye. Much of this, as has been formerly mentioned, depends upon, and is regulated by, the peculiar style of the picture and the skill of the engraver.

"As lines seem to partake of motion, in proportion as they deviate in gentle bendings from the straight and precise; even so also in the motion of water seemingly increased, whether they undulate with the simplest wave, or swell with the fierce and tempest-curled surge. This character is sufficiently illustrated in the works of Balechow and Woollet.

"In the late Mr Brown's large print of St John preaching in the wilderness, no engraver has ever more fully displayed the true spirit of Salvator Rosa, particularly in the original mode of treating the rocks, and the bold style of the surrounding scenery; in short, in the aggregate it is a chef d'œuvre unparalleled in any country. This is freely acknowledged, not only by every man of taste, but by the first landscape engravers.

"But Brown was perhaps less happy in the companion to the above, from the celebrated Both, by adapting a similar mode to that finished and delicate painter. For the style should ever vary with the subject.

> Whate'er Lorrain light touched with softening hue,
> Or savage Rosa dash'd, or learned Poussin drew.

"His admirable etchings of the cottager and its companion, and the Celadon and Amelia, are fine specimens of his discriminating powers, and characterized with so near an approach to truth, that we cannot help exclaiming with the poet,

> He sees no other, nature's self who sees.

"The engraving of the above subjects was finished by the matchless Woollet with the same happy taste. And it must be acknowledged that it is but seldom that we see so many excellencies united; for it is equally rare to see the finest engraving united to the finest drawing, as to find it in painting combined with the choicest colouring; yet each have their decided fascinations in the gallery, the cabinet, or the portfolio.

"Woollet, whose works abound with nerve and intelligence in point of character, his style of landscape is delightfully descriptive; whether rocks, water, trees, or sky; as the Niobe, the Ceyx and Alcyone, and other masterpieces from the great Wilson, evince. In the winter scene from Smith of Chichester he has admirably contrived to convey the effect of the drifted snow by delicate dotting; and with no less precision he has described the transparent ice with clear lines. Of trees, he was the first that ever faithfully characterized the graceful larch; as may be seen in his views of the noblemen's seats. In the print of the fishery he is indebted to the masterly etching of John Brown, particularly the shipping, in which there is perhaps no subject more articulate and perspicuous. The engraving of this subject is finished by himself. In his figures he was the founder of a style most happily adapted for modern dresses and historical portraiture; a style in which he moved with unrivalled reputation. His print of the death of General Wolf, painted by Mr West, is an admirable example, and does honour to the British nation. It occupied him no less than four years. The print of the battle at La Hogue is another fine specimen of his knowledge of linear discrimination. In short, when we consider the talents of this artist, it is difficult to decide whether he most excelled in modern history or landscape. The art has to regret that he, who was so eminently qualified to adorn any line of the profession, has left no works in ancient history. We have little doubt, from his knowledge, and a real love of the art, he would have left a sufficient monument in that department also for the pleasure and contemplation of the real connoisseur and of posterity. Engraving in this country sustained a heavy loss when he died; and if the death of so excellent an artist may be considered as a public loss, it is certainly the more felt with respect to Woollet, who died while he was yet improving in that excellence.[1]

"Chattelaine has been termed a mannerist in his drawings, but he must certainly be allowed to be an excellent one; his etchings are variety itself. Perhaps in the department of etching no artist has so happily translated the pictures of Claude de Lorraine as Francis Vivares; that is, with respect to aerial perspective, the peculiar characteristic of Claude. But his merits are not confined to this master alone; for he followed Ruysdale, Berghem, Gainsborough, and Cuyp, with great success. He has such a free delivery of style, that almost every one who examines his works is irresistibly impressed with an idea of performing the very same. Few artists, it has been mentioned, have excelled in the etching department. We cannot, however, omit the name of Peranezzi; who, to originality of style, which is apparently spontaneous, joins a certain grandeur which had never been surpassed. He has transmitted to posterity so spirited a representation of the Greek and Roman edifices and ruins, that travellers have often confessed that they have raised their ideas beyond the magnitude of the superstructures themselves. It is certain that in works of this stupendous nature, a degree of ruggedness in the execution corresponds with the sublimity of the subjects, and thus produces a still greater power over the mind than if they had been more polished. Some have censured his figures, and not without cause. This defect has been ingeniously palliated by an excellent artist, M. Bartolozzi. "For," said he, "if the purchasers of the works of Peranezzi get so much for their money in the building way, the figures may be supposed to be given for nothing." Doubtless those vast piles of perishing grandeur were never more judiciously presented to the eye than by this astonishing artist, or better calculated to affect the mind by calling forth its most sublime ideas.

---

[1] Although we are now contemplating linear engraving, it is but proper here to observe, that chalk engraving, mezzotinto, and aquatinta, have also made ample improvements in this country in their various styles of excellence.

"We have another striking instance of spirited etching in a different pursuit of the art, in the works of Ridinger, a name which brings along with it all the savage scenery of nature.

> Assembling wolves in raging troops descend.........
> They fasten on the steed, and pierce his mighty heart.

For we shall ever find some peculiar beauty to admire, even in the slightest productions of genius, as well as in the most perfect productions of the burin.

"There are few artists who do not regret that etching was unknown to Bolswert, who has done so much without its aid; from which we may easily suppose how much more he could have effected with this charming acquisition. For the truth of this remark we may appeal to his landscapes from Rubens, his animated portraits from Vandyke, and his productions from the Flemish school of history, particularly his large print of the taking down from the cross, from Rubens.

"There is a fine instance of linear effect in a print of a Flemish conversation piece by Wille. One of the figures is drinking out of a glass, and the artist has most deceptively described the texture of the drinker's face through the glass. In the same print a female figure shows great skill in this way; even the floor is characterized by lines; and the whole strongly marks the most proper mode of treating subjects of a mere local nature. The beautiful print of the *Petit Physicien* is also an admirable imitation, particularly the little pellucid globule which has just mounted from the shell. When lines are engraved in a square acute method of crossing, they generally convey the idea of hardness to the subject represented. The scientific Picart seems to have been so much aware of this, that in a print of his engraving of a large marble group of horses, from the animated chisel of Perriere, he adopted this style in order to heighten the imitation.

"Mason's print of Marshal Harcourt is one of the many fine efforts of portrait engraving; and although it was executed at an early period of the art, it abounds with no small degree of taste. The celebrated print (called the table-cloth), from Titian, of the Last Supper, also contains a considerable degree of linear discrimination, although he sometimes carries it to affectation. He is rather singular in his mode of engraving hair. Yet the portraits of Marshal Harcourt and Brisasiere the secretary may be deemed exceptions.

"While, by the magic of his tooling, he is too apt at times to give his works indiscriminately the appearance of bronze; and we frequently find the same in the figures of Balechow; but it seems to have been reserved for Strange to give the softness of carnation to copper, and to Woollet to give force and clearness with discriminating taste; Bartolozzi in his lines, elegance, delicacy, and drawing; while the works of Audran teem with boldness and simplicity. In the prints of Sir Robert Strange, the greatest excellence is perhaps his rich and harmonious tones, as well as the whole effect, which is supported by an expressive style, which he seems in a great measure to have invented for his most favourite painters, Correggio, Titian, Guido, and Guerchino. The softness, the gusto, and the flowing draperies in the works of these masters, were his delight. His sleeping Cupid from Guido, and the prints of the Venus and Danaë from Titian, will ever be esteemed as *chef d'œuvres* in the linear art."

Having thus attempted to fulfil our original intention of discriminating the most expressive combinations of lines, and of analyzing and illustrating their various powers and effects in engraving, we shall now conclude these observations; and if, from the nature of the subject, and from the limits of the sketch, we have failed in marking every brilliant star in the galaxy of the art, it must at least be acknowledged that we have not omitted some of those of the first magnitude.

ENGRAVING *upon Steel.* On the first discovery of the art of printing from engraved metals, experiments would most probably be made with a view of ascertaining the fittest metal for the purpose. Indeed it is known that copper, tin, and silver were employed by the early artists; and there are some prints by Albert Durer which are considered as impressions from plates engraved or etched on steel. In the collection of Albert Durer's prints in the British Museum there are five of these prints, the chief of which are, *Christ in the Garden*, a print six inches by eight and a half, dated 1515; the *Lady and the Monster*, twelve inches by eight and a fourth, dated 1516; and the *Canon*, twelve and three fourth inches by eight and a half, dated 1518.

But, for the usual purposes of engraving, copper has, till within a few years, been supposed to have some advantages, which have led to its being nearly always employed in preference to other metals; and in one instance only have we found that steel-plate was used for engraving upon in this country, before the late attempts to prevent the forgery of bank-notes. The plate we allude to is the Ceiling of the Star Chamber, in the *Topographical Illustrations of Westminster*, engraved by Mr J. T. Smith in 1805.

The great expense of renewing plates for bank-notes, when any superior engraving is introduced for rendering imitation difficult, suggested the idea of employing a harder material than copper to engrave upon. Steel-plate was tried, and found capable of affording from twenty to thirty times the number of impressions that could be obtained from a plate of copper, whilst it was not much more difficult to engrave upon. The advantages derived from employing steel were first made public in this country in 1818, by the inquiry respecting the prevention of forgery, instituted by the Society for the Encouragement of Arts in London, when a specimen of engraving on soft steel was presented to the society by the late Mr Charles Warren; and it appeared from evidence collected by the committee, that notes with ornamental borders, printed from steel-plates, were then in use in America. Soon after this period Messrs Perkins and Fairman from America, in conjunction with Mr Heath, an eminent engraver of London, formed an establishment for printing notes and other engravings from steel blocks.

The methods of engraving on steel, adopted by Warren and others, were similar to those employed in engraving on copper; differing only as far as was necessary on account of the nature of the material and the process of hardening the plates in use in the earlier stages of this invention. In addition to these methods, Perkins, Fairman, and Heath employ a mechanical process for increasing the number of impressions. They first make the engraving on a thick plate of soft steel; the plate is then hardened, and the impression is transferred, in a spring press, to the surface of a soft steel cylinder, by rolling the cylinder repeatedly to and fro on the engraved plate, under a very considerable pressure. The transfer thus obtained is in relief, and the cylinder being hardened, it is made, by the same spring press, to repeat as many impressions as may be desired on soft steel, or on copperplates, for the purpose of printing from. They usually impress steel blocks, each of which will afford several thousand impressions; and when the cylinder becomes worn by transferring, a new one may be impressed from the original engraving; and, consequently, an inconceivable number of prints may be obtained from one original plate.

It ought, however, to be remarked, that an engraving cannot be transferred from steel to steel without injury; and that the injury will be greater in proportion to the delicacy of the work. Indeed, where engravings are to be considered as works of art, it will always be preferable to engrave or etch on tempered steel, and print from it without hardening. A sufficient quantity of impressions may thus be obtained, and of a superior kind; because steel being harder and more compact than copper, it is consequently less worn by the process of wiping off the printing ink either with the cloth or the hand.[1] But the power of transferring is of great value in all cases where a great number of impressions is the chief object desired, as in notes, plates for school-books, ornamental borders for pottery, labels, and the like.

In preparing steel-plates, either for engraving or etching, the surface should be well polished, so as to render it compact, of an equable degree of hardness, and perfectly smooth. The same tools are used as for copper, but they should be of the kind of steel which is endowed with the greatest degree of toughness. When a plate is to be etched, the point which removes the varnish should be sufficiently hard to penetrate the polish on the surface of the plate; the acid will then bite more freely, and to a greater depth, without spreading so as to produce a broad and shallow line. A point of diamond is, we believe, sometimes employed, particularly where the lines are drawn with the *ruling-machine* invented by Mr Wilson Lowry, the founder of a new school of engraving, which has been of infinite use in diffusing correct taste in architecture and sound knowledge in mechanics. The same ingenious artist observed, in the first etchings on steel, that the lines were broad without depth; and, in consequence, tried to find a *menstruum* which would answer the purpose better than the common acids. In this he perfectly succeeded, and was enabled to bite the lines deep, and yet preserve the desired degree of fineness.

Of the common acids, diluted muriatic acid seems to answer best, but diluted nitric and nitrous acids produce nearly the same effect.

When the graver is to be much employed on a plate, it should be annealed, in order to render it uniformly soft. The plate, after being engraved, may be hardened most effectually, and with the least injury to the engraving, or risk of warping the plate, by heating it in a metallic bath, and quenching the whole in a cooling fluid. A bath of the fusible alloy of lead, tin, and bismuth, which Dr Wollaston proposed for hardening delicate steel-work, will perhaps answer better than any other. (See Cutlery.) It will always be an advantage to employ a perfectly fluid medium for cooling; and we have reason to conclude, from some hasty experiments, that water heated to its boiling point is better than cold water for cooling steel. The quick abstraction of heat, by converting water into steam, seems to have more effect than the mere cooling power of a large body of cold water. Plates to be hardened should be about half an inch thick.

If plates are not to be transferred, there is some disadvantage in employing thick ones; and more especially in cases where an alteration may be necessary, or a mistake is to be rectified. In a thin steel-plate it is as easy to rectify an error as in copper; but in a thick one it is a very troublesome process.

Mezzotinto engraving on steel is also found to answer well; and upon that metal some very fine prints have lately been done; and the great number of impressions which a steel plate affords will cause this beautiful style of engraving to be more generally cultivated.

As printing from engraved steel is now much used as a means of preventing forgery, we shall close this article with a few remarks on that subject. It appears to us that there should be nothing complex in the figures which are selected for the engraving; their excellence should consist in the perfect evenness and parallelism of lines, whether straight or curved; but curved lines of difficult kinds should be preferred. Many crossings render a pattern intricate and confused; they distract the attention and dazzle the sight. Wavy patterns, with scattered lights, have the same effect. In such cases it is difficult to compare one specimen with another, and a general imitation is not so easily detected. It will be desirable to unite the work of an artist to that of a mechanical engraver; and in such cases the subject should be of sufficient size to allow of its being distinctly made out, because it will increase the difficulty of imitation. Where the circulation of notes is limited, good engraving on the note will be some check upon forgery; but the notes of different banks should be made as distinct as possible, instead of the same work being introduced in different notes, as may easily be done with steel cylinders. Where a whole empire is served with one kind of notes, the temptation to forge is so great that it cannot perhaps be altogether prevented; and, therefore, whilst every proper expedient should be used to increase the difficulty of forgery, no apparent difficulty of copying should render bankers and others less on their guard against it.

See *Report of the Committee of the Society of Arts, on the Mode of Preventing the Forgery of Bank-Notes*, 8vo, London, 1819; *Edinburgh Philosophical Journal*, vol. iii. p. 140.

Engraving *upon Glass*. See Glass, *Engraving on*.

Engraving *on Precious Stones* is the representing of figures, or devices, in relief, or indented, on various kinds of hard polished stones.

The art of engraving on precious stones is one of those in which the ancients excelled; there being various antique agates, cornelians, and onyxes, which surpass any thing of the kind which the moderns have produced. Pyrgoteles among the Greeks, and Dioscorides under the first emperors of Rome, are the most eminent engravers we read of. The former was so esteemed by Alexander, that he forbade any body else to engrave his head; and Augustus's head, engraven by the latter, was deemed so beautiful that the succeeding emperors chose it for their seal.

All the polite arts having been buried under the ruins of the Roman empire, that of engraving on stones met with the same fate. It was retrieved in Italy at the beginning of the fifteenth century, when one John of Florence, and after him Dominic of Milan, performed works of this kind no way to be despised. From that time sculptures of this kind became common enough in Europe, and particularly in Germany, whence great numbers were sent into other countries; but they fell far short of the beauty of those of the ancients, especially those executed on precious stones; for, as to those on crystal, the Germans, and after them the French, &c. have succeeded well enough.

---

[1] A steel-plate, which had not been hardened, has been known to afford 95,000 impressions without material injury.

In this branch of engraving artists make use either of the diamond or of emery.

The diamond, which is the hardest of all stones, is only cut by itself, or with its own matter. The first thing to be done in this branch of engraving is, to cement two rough diamonds to the ends of two sticks large enough to hold them steady in the hand, and to rub or grind them against each other till they be brought to the form desired. The dust or powder which is rubbed off serves afterwards to polish them; and this is performed with a kind of mill that turns a wheel of soft iron. The diamond is fixed in a brass dish, and, being thus applied to the wheel, it is covered with diamond dust, mixed with oil of olives; and when the diamond is to be cut facet-wise, first one face, and then another, is applied to the wheel. Rubies, sapphires, and topazes, are cut and formed in the same way on a copper wheel, and polished, with tripoli diluted in water. As to agates, amethysts, emeralds, hyacinths, granites, rubies, and others of the softer stones, they are cut on a leaden wheel, moistened with emery and water, and polished with tripoli on a pewter wheel. Lapis-lazuli, opal, and some others, are polished on a wooden wheel. To fashion and engrave vases of agate, crystal, lapis-lazuli, or the like, a kind of lathe, like that used by pewterers, is made use of to hold the vessels, which are to be wrought with proper tools; that of the engraver generally holds the tools, which are turned by a wheel; and the vessel is held to them to be cut and engraved, either in relief or otherwise, the tools being moistened from time to time with diamond dust and oil, or at least emery and water. To engrave figures or devices on any of these stones when polished, such as medals, seals, and the like, a little iron wheel is used, the ends of whose axis are received within two pieces of iron, placed upright, as in the turner's lathe, and so adjusted as to be brought closer, or set further apart, at pleasure. At one end of the axis are fitted the proper tools, which are kept tight by a screw. Lastly, the wheel is turned by the foot, and the stone applied by the hand to the tool, and shifted and conducted as occasion requires.

The tools are generally of iron, and sometimes of brass: their form is various, but it generally bears some resemblance to chisels, gouges, and the like. Some have small round heads like buttons, others like ferrels, to take the pieces out, and others again flat. When the stone has been engraven, it is polished on wheels of hair-brushes and tripoli.

ENGUERA, a town of Spain, in the province of Valencia, with 5000 inhabitants. About 3000 weavers and spinners are employed in its manufactories of cloth.

ENGUICHE', in *Heraldry*, is said of the great mouth of a hunting horn, when its rim is of a different colour from that of the horn itself.

ENHARMONIC, in *Music*. See MUSIC.

ENIGMA. See ÆNIGMA.

ENKHUYZEN, a city of North Holland, in the circle of Hoorn. It is situated on the Zuyder Zee, and is strongly fortified both on the land and on the sea side. It contains 2600 houses and 6950 inhabitants, who carry on extensive fisheries, have considerable trade in cheese and wood, and refine much salt. It has considerable reputation for its horticultural products. Long. 4. 5. E. Lat. 52. 42. 22. N.

ENMANCHE', in *Heraldry*, is when lines are drawn from the centre of the upper edge of the chief to the sides, to about half the breadth of the chief, signifying sleeved, or resembling a sleeve; from the French *manche*.

ENNEAGON, in *Geometry*, a polygon with nine sides.

ENNIUS, Q., a celebrated poet of Rhudiæ, in Calabria, a province of the south of Italy, to the east of Tarentum, born 239 before Christ, in the consulship of Q. Valerius Falto and C. Mamilius Turrinus. Descended from one of the petty princes who ruled over this portion of Italy, he had inherited nothing from them except the barren nobility of blood. His early years, if not spent in the camp, must at least have been disturbed by rumours of war and threatened invasion. The inroad of Hannibal, 218 before Christ, and the fearful struggle which ensued between the two powerful nations of Rome and Carthage, could scarcely have taken place without extending its shock to the most remote villages of Italy. In the earlier period of the contest, we are ignorant of the side to which Ennius adhered; but we find him, in 204 before Christ, when he was thirty-five years of age, serving as a soldier in Sardinia, with such distinction as to attract the notice of Cato the elder, at that time commander of the island. By him he was brought to Rome, where his high character and literary attainments introduced him to the acquaintance of the most distinguished characters of that city. Scipio Africanus the elder became his intimate friend. At Rome he seems to have employed his time in extending the knowledge of the Greek language amongst the younger branches of the nobility. Even Cato did not disdain to become his pupil; and the example which he thus set no doubt tended much to divert the minds of his countrymen towards pursuits of a more refined and intellectual character than had hitherto engaged their attention. His genius procured him the freedom of the city, an honour which had not yet become worthless from an indiscriminate distinction. He passed into Ætolia, in 183 B. C., with the consul Fulvius, to whose care the war in that country was intrusted; and he no doubt seized this opportunity of visiting the various states of Greece. He seems, however, to have returned to Rome, where he died of the gout in 169 B. C., in the seventieth year of his age. Scipio, before he died, had expressed a wish that their bodies should rest in the same grave; and we know that a statue was erected to his honour on the tomb of the Scipios.

Ennius must be considered as the father of Roman epic poetry; and the eminent services which he performed for the literature of Rome were fully appreciated by ancient writers. Throughout his works there ran a strain of noble and passionate feeling. The language, though sometimes rough and unpolished, was full of power, and even of sublimity. The structure of the verse was more regular, from the introduction of hexameters, than that in which his predecessors had sung. The principal work, from which we have numerous fragments, was the *Annales*, an epic poem in eighteen books, in which Ennius sang the history of Rome, from its foundation till his own times. In another work, written in catalectic tetrameter, he celebrated the deeds of the elder Scipio. Besides, he had composed satires and other minor poems, which seem, however, to have been rather translations from the Greek writers: *Edesphagetica*, or *Phagetica*, in hexameters, a gastronomic poem after the Greek of Archestratus; several epigrams; *Epicharmus*, a didactic poem on the nature of things, in trochees and hexameters, from the Greek of Epicharmus; *Protrepticus*, of a moral nature; *Præcepta*, perhaps the same as the preceding; *Asotus*, or *Sotadicus*; also a Latin prose translation of the well-known Greek work of Euhemerus on the Gods; and perhaps in prose, a work on the Rape of the Sabines.

His tragedies seem to have been generally composed in imitation of the Greek dramatic writers, Æschylus, Sophocles, Euripides, and others. Those whose titles have been preserved to us are the following: Medea, Iphigenia (after Euripides), Achilles, Ajax (after Sophocles), Telamon, Hectoris Lustra, Alexander, Andromache, Hecuba, Eumenides (after Æschylus), Dulorestes, Erechtheus, Cresphon, Athamas, Andromeda, Telephas, Thyestes, Phœnix, Melanippa, Alcmæon, Cressæ, Alcestis, Nemea, Ilione or Polydorus, and Antiope.

The titles and fragments of several of his comedies have also been preserved, which, like his tragedies, are copied from the Greek dramatic writers of the new comedy. They are, Amphithraso, Ambracia, Pancratiastes.

The fragments of Ennius were published by Columna (at Naples, 1590), and again in the *Corpus Poetarum* by Hesselius (4to, Amstel. 1707). The fragments of the Annals were collected and published by P. Merula (Lugdun. Bat. 1595), and by Spangenberg (Leipsic, 1825). The tragedy of Medea was published in part, with a selection of other fragments, and a learned commentary, by H. M. Plauck. (Hanover, 1807, 4to.)

For a detailed account of the life and character of Ennius, the reader may consult W. Fr. Kreidmann *Orat. de Q. Ennio*, Jenæ, 1754; Krause, *Vitæ et Fragmenta veterum Historicorum Romanorum*, Berlin, 1833, 8vo; also Fabricii *Bibliotheca Latina* (1 vol. p. 664), Hamburg, 1721; also *Geschichte der Romischen Literatur* von Bahr, Carlsruhe, 1832.

ENORE, a village of Hindustan, in the Carnatic, eight miles north from Madras, and situated on the shore of a salt-water lake, abounding with oysters and other fish. It is a great resort of company from Madras, who meet here to fish, and to take the diversion of sailing in pleasure boats; an enjoyment which is quite impracticable on the coast, owing to the almost constant surf which beats upon the shore. The situation is on a flat sandy bank, where there are about a hundred native huts.

ENOS, a city of Turkey in Europe, in the district of the Sea of Marmora. It is on a river of the same name, but called by the Turks Boris Korfusi. It has a good harbour, frequented by ships of all nations, which take cargoes of wool, camels' hair, cotton, hides, morocco-leather, silk, copper, and wax. It is said to contain 7000 inhabitants. Long. 25. 56. 1. E. Lat. 40. 43. 42. N.

ENOTAEVSK, a town of Asiatic Russia, in the government of Caucasus, situated on the Volga, seventy-two miles N. N. E. of Astracan. Long. 46. 19. E. Lat. 47. 15. N.

ENOWTAWKAIA, a village and wooden fortress of Asiatic Russia, in the province of Astracan. The fortress was built in 1741, for the Kalmucs. It is twenty miles S. E. of Tchernoyar.

ENS, among metaphysicians, denotes entity, being, or existence. This the schoolmen call *ens reale* and *ens positivum*, to distinguish it from their *ens rationis*, which is only an imaginary thing, or exists but in the imagination.

ENS, a river in the Austrian dominions, which falls into the Danube. It is chiefly remarkable because it is the boundary line between two large provinces of that empire. These are distinguished by the names of the Upper and Lower Ens. The province of the Lower Ens is nearly in the centre of the monarchy. It is bounded on the north by Bohemia and Moravia, on the east by Hungary, on the south by Steyermark, and on the west by the Upper Ens. It extends over 8012 square miles, and is divided into four circles, besides one consisting of the city of Vienna and its suburbs. The names of those circles are, the Upper and the Lower Vienna Forests, and the Upper and the Lower Manhartsberg. In 1816 the province contained 1,045,412 inhabitants, who have increased considerably since that period, and occupied 35 cities, 339 market-towns, and 4286 villages, in which were 148,172 dwelling-houses.

The face of the country is generally mountainous, although the warm valley of the Danube and some others contain land equal to any of Europe in productive power, and spots whose picturesque beauty is excelled by few in any country. There are a great number of smaller streams which empty themselves into the Danube, the banks of all which are fertile and pleasant. The mountain ranges are a part of the Noric Alps, running for the most part perpendicular to the river, and varying in height from 4400 to 6500 feet. The soil varies greatly, and as a whole, including the mountain districts, cannot be considered as fertile. The surface of the province appears by the cadastre to be 5,023,580 English acres, and the rivers, lakes, roads, rocks, and waste lands, with the site of the cities, towns, and villages, occupy 1,046,860, or somewhat more than one fifth of the whole. The rest of the land is thus appropriated: 2,244,508 acres are under the plough, 96,757 are in gardens, 137,656 are in vineyards, 666,900 are in meadows, 467,254 in upland pastures, and 1,505,440 are woods and forests. Although agriculture is not worse conducted than in Germany generally, the product of corn is unequal to the demand for it; and it is calculated that wheat and rye scarcely yield more than five times the seed. The breeds of cattle are by no means good, and neither sheep, oxen, nor cows, are abundant. Poultry and river fish are plentiful, as are also game both of the feathered and four-footed kinds. Wine and fruits are copiously produced, and much of both, after supplying the capital, is sent to the other provinces. The want of wood for fuel is complained of, and said to be constantly increasing, although of late years improvements have been introduced in the management of the woods, roads made to many places that were before inaccessible, and floats formed on many of the small rivers, to augment the supply. The whole province is a manufacturing district, and furnishes cotton, linen, and woollen cloth, silk goods, iron and copper wares, gold, silver, and plated articles, glass, hats, paper, hosiery, and the various smaller articles of necessity or luxury. The chief commodities exported are wine, saffron, mustard, and wool. The imports consist of East and West India articles, silk, corn, flour, cattle, wood, and salt. The city of Vienna has good roads from it to the most distant parts of the empire, on which, as well as on the rivers, there is a very great traffic.

Province of the Upper Ens.

The province of the Upper Ens is the westernmost part of the Austrian dominions, with which have been incorporated a part of the Valley of the Inn, which, before 1779, belonged to Bavaria, and the larger portion of the duchy of Salzburg, ceded to Austria in 1816. It is bounded on the north by Bohemia, on the north-east by the province of the Lower Ens, on the south-east by Steyermark, on the south by Illyria, on the south-west by the Tyrol, and on the north-west by the kingdom of Bavaria. It is 7568 square miles in extent. It is divided into five circles, namely, the Mühlvierthal, the Hausruck, the Traun, the Innvierthal, and the Salzach or Salzburg. It contained in 1816 seventeen cities, 122 market-towns, 7725 villages, and 124,606 houses, inhabited by 756,890 individuals, since which they have rapidly increased.

The southern part of the province is a mountainous district, covered with a portion of the Noric Alps, in which are Glockner on the frontier of the Tyrol, 11,700 feet in height; the Viehbachhorn, 11,058; and several others exceeding 8000. Some of them are covered with perpetual snow, and have between them glaciers or fields of ice of more than sixty square miles in extent. On the north of the province the mountains which separate it from Bohemia are lower, but fill almost the whole circle of Mühlviertḥal. The province is well watered, having, besides the Danube, four other navigable rivers which discharge their waters into it. No country presents more lakes, and none are of greater beauty than the Traun, the Kammersee, the Mondsee, and the Hallstadtsee.

A country so mountainous has little opportunity of practising agriculture, and, with the exception of Salzburg, the corn is not supposed to produce more than four times the seed. The province contains 5,751,900 acres, of which 1,464,750 are under the plough, 44,840 are in gardens, 145 in vineyards, 649,967 are meadows, 1,393,670 upland pasture, and 1,697,040 woods. The remainder is occupied with lakes, rivers, glaciers, roads, and sites of cities and towns. One of the chief productions of the province is salt, which is made from brine springs upon a very extensive scale at Hallein. In some parts are mines now worked. These produce annually 2400 ounces of gold, 6400 ounces of silver, 886 quintals of copper, 490 quintals of lead, and 14,461 quintals of iron, besides arsenic, vitriol, sulphur, and gypsum. The iron manufactures, and particularly that of knives, give employment to thousands of families. There are also many mills on the various streams, for spinning cotton, linen, and woollen yarn. It is said that the woollen manufacture alone supports more than 25,000 families. In the cities of Lintz, Salzburg, and Steyer, there is much transit trade, both by the rivers and by the three great and excellent roads which traverse the province.

Ens, a city of Austria, in the province of the Lower Ens. It stands near the influx of that river into the Danube, and contains 380 houses, with 2951 inhabitants employed in linen weaving and in breweries. Being on the great road to Vienna, it has upwards of twenty inns and hotels. Long. 14. 21. E. Lat. 48. 13. N.

ENSEELED, in *Falconry*, is said of a hawk that has a thread drawn through her upper eye-lid, and made fast under her beak, to take away the sight.

ENSHAM, a town of the county of Oxford, in the hundred of Wootten, sixty-one miles from London. It is situated on the river Isis or Thames, and on the great road from London to Worcester and Birmingham, from which it derives some traffic. It had formerly an extensive abbey, the remains of which may still be traced. The population amounted in 1801 to 1166, in 1811 to 1418, in 1821 to 1705, and in 1831 to 1858.

ENSIGN, in the military art, a banner or colours under which soldiers are ranged, according to the different companies or parties to which they belong.

The Turkish ensigns are horses' tails; those of the Europeans are pieces of taffety, with divers figures, colours, arms, and devices thereon. Xenophon tells us that the ensign borne by the Persians was a golden eagle on a white ground; the Corinthians bore the winged horse or Pegasus on theirs; the Athenians an owl; the Messenians the Greek letter M; the Lacedæmonians the Λ. The Romans had a great diversity of ensigns, the wolf, minotaur, horse, boar, and at length the eagle, where they stopped. This was first assumed in the second year of the consulate of Marius. A military ensign on a medal of a Roman colony denotes it a colony peopled with old soldiers.

Ensign is also the officer who carries the colours, being the lowest commissioned officer in a company of foot, subordinate to the captain and lieutenant.

Naval Ensign, a large standard or banner hoisted on a long pole erected over the poop, and called the *ensign staff*. The ensign is used to distinguish the ships of different nations from each other, as also to characterize the different squadrons of the navy. The British ensign in ships of war is known by a double cross, viz. that of St George and St Andrew, formed upon a field which is either red, white, or blue.

ENT, Sir George, an eminent English physician, born at Sandwich, in Kent, in 1604. He was educated at Sidney College, Cambridge, and, having afterwards travelled into foreign countries, received the degree of doctor of physic at Padua. After his return he obtained great practice, was made president of the college of physicians in London, and at length received the honour of knighthood from King Charles II. He was extremely intimate with Dr Harvey, whom he learnedly defended, in a piece entitled *Apologia pro Circulatione Sanguinis, contra Æmilium Parisanum*. He also published *Animadversiones*, and some observations in the Philosophical Transactions. Glanville, speaking in his *Plus Ultra* of the modern improvements in anatomy, numbers Sir George Ent, Dr Glisson, and Dr Wallis, with the most celebrated discoverers in that science. The two former were amongst the first members of the Royal Society. Sir George Ent died in October 1689.

ENTAIL, in *Law*. See Tailzie.

ENTHUSIASM, in a religious sense, implies a transport of the mind, by which it fancies itself inspired with some revelation, impulse, or the like, from heaven. "In all ages," says Locke, "men in whom melancholy has mixed with devotion, or whose conceit of themselves has raised them into an opinion of a great familiarity with God, and a nearer admittance to his favour than is afforded to others, have often flattered themselves with a persuasion of an immediate intercourse with the Deity, and frequent communications from the Divine Spirit. Their minds being thus prepared, whatever groundless opinion comes to settle itself strongly upon their fancies is an illumination from the Spirit of God; and whatsoever odd action they find in themselves a strong inclination to do, that impulse is concluded to be a call or direction from heaven, and must be obeyed. It is a commission from above, and they cannot err in executing it. This I take to be properly enthusiasm, which, though arising from the conceit of a warm and overweening brain, works, when it once gets footing, more powerfully on the persuasions and actions of men than either reason or revelation, or both together, men being most forwardly obedient to the impulses they receive from themselves."

ENTHYMEME, in *Logic* and *Rhetoric*, an argument consisting only of two propositions, an antecedent, and a consequent deduced from it. The word is Greek, ενθυμημα, formed of the verb ενθυμεισθαι, *to think, conceive*, a compound of εν, and ϑυμος, *mind*.

The enthymeme is the most simple and elegant of all argumentations, being that which a man, in arguing closely, commonly makes, without attending at all to the form. Thus, the verse remaining of Ovid's tragedy entitled *Medea* contains an enthymeme: *Servare potui, perdere an possum rogas*,—"I was able to save you, consequently to have destroyed you." The beauty would have been lost had all the propositions been expressed; the mind is displeased with a rehearsal of what is nowise necessary.

Sometimes also the two propositions of an enthymeme are both included in a single proposition, which Aristotle calls an *enthymematical sentence*, of which he gives this instance: *Mortal, do not bear an immortal hatred.* The whole enthymeme would be, *Thou art mortal, let not, therefore, thy hatred be immortal.*

ENTLIBUCH, a bailiwick in the canton of Lucerne, in Switzerland, extending over 110 square miles, and containing five parishes, with 12,550 inhabitants.

ENTOMOLOGY.

Definition.

Entomology (from ἔντομον, *insect*, and λογος, *discourse*), is that branch of natural science which treats of the history and habits of the insect tribes. Its subjects are the most numerous and diversified of any of those topics which engage the attention of the student of nature; and as they exemplify in a most surprising and admirable manner, both by their structure and instincts, the wisdom of the author and creator of all things, and form a highly interesting department of human knowledge, we deem their elucidation deserving of a lengthened dissertation.

The English term insect is no doubt derived from the Latin word *insectum* or *intersectum*, signifying *cut into* or intersected, in allusion to the obvious divisions of head, thorax, and abdomen, of which their general forms consist. The Greek word bears the same signification.

CHAPTER I.

DEFINITION OF INSECTS—THEIR ORDERS EXPLAINED—AND THEIR STUDY DEFENDED.

In the article Animal Kingdom of this work (see vol. iii. p. 179), we have given a view of the primary divisions of the subjects of zoological science. The third primary division, that of the articulated animals, consists of four great classes:—1. *Annelides*, such as serpulæ, nereids, leeches, earthworms, &c.; 2. *Crustacea*, such as crabs, lobsters, and shrimps; 3. *Arachnides*, such as spiders, scorpions, and mites; and 4. *Insecta*, or true insects, such as beetles, butterflies, and moths. The class Insecta of Linnæus included not only those last named, but also Crustacea and Arachnides, and was thus almost co-extensive with what we now regard as a primary division under the term *Articulata*. We have, however, already discussed those two branches as distinct classes, under their respective titles (see Arachnides and Crustacea), and we shall not repeat the important characters by which they are distinguished from genuine insects.

The term insect was anciently applied to a much more extended series of beings than are now included under that designation. It seems to have comprised whatever was destitute of an internal skeleton, and exhibited a body composed of articulated parts. In this sense it accords with its application in the writings of Aristotle and Pliny, with certain restrictions however, for these authors were in advance of their successors, in as far as they distinguished the Crustacea from insects. Swammerdam and Ray adopted the definition of the ancient authors, but erred in classing the Vermes or worms with insects, a combination which does not appear for certain to have entered into Aristotle's views. Linnæus wisely separated these two classes, but at the same time injudiciously joined the Crustacea with insects, placing them in his order *Aptera*, along with spiders and scolopendræ. Fabricius in that respect followed the same general plan, and included all those living creatures in the same class, notwithstanding the better example shown by Brisson, who had separated all the species possessed of more than six feet, that is, the Crustacea and Arachnides of Lamarck. Since the death of the great Swedish naturalist, our improved knowledge of the anatomy and physiology of the invertebrated classes has thrown a clearer light upon the subject, and many modifications have taken place in the arrangement of the insect tribes.

Insects, properly so called, may be defined as *animals without vertebræ, six-footed, with a distinct head furnished with two antennæ and a pair of composite immoveable eyes, and breathing through stigmatic openings which lead to interior tracheæ.*[1]

As we shall have occasion to mention many terms which may not be familiar to the general reader, we deem it advisable, instead of taking his knowledge for granted, to commence with a brief enumeration and explanation of the various *orders* in Entomology, so that their names, when subsequently brought forward, may be associated with some definite idea. We shall consider all insects as included under eleven different orders, as follows.

1. Coleoptera (from Κολεος, *a sheath*, and πτερα, *wings*), including all those kinds commonly called *beetles*. Their membranous wings, which are the true organs of flight, are protected by a superior and anterior pair of harder consistence, called elytra. They are all masticators, and are provided with mandibles and maxillæ. Plates CCXXI–VII.

2. Orthoptera (from ορθος, *straight*, and πτερα, *wings*), including crickets, grasshoppers, locusts, &c. The upper wings are of the consistence of parchment, reticulated, and more or less incumbent. The mouth is provided with mandibles and maxillæ. Plate CCXXVIII.

3. Hemiptera (from ἡμισυ, *the half*, and πτερα, *wings*), including the cimices or bugs, the water scorpions, cicadæ or froghoppers, aphides, &c. A portion of their upper wings is frequently membranaceous, or of the same consistence as the inferior pair. The mandibles and maxillæ are replaced by a sheath and sucker. Plate CCXXIX.

4. Neuroptera (from νευρον, *nerve*, and πτερα, *wings*), including libellulæ or dragon-flies, ephemeræ, &c. Both pairs of wings are membranous, naked, and finely reticulated. Mouth adapted for mastication, and furnished with mandibles and maxillæ. Plate CCXXX.

5. Hymenoptera (from ὑμην, *a membrane*, and πτερα, *wings*), containing wasps, bees, ichneumon-flies, &c., and characterized likewise by membranous naked wings, which

---

[1] The above definition excludes those many-footed species called *Juli* and *Scolopendræ*, which, though still included by some modern writers among insects, were established as a distinct class by Dr Leach (*Edinburgh Encyclopædia*, vol. viii.; and *Linn. Trans.* vol. ix.) under the title of *Myriapoda*, and were recognised as such by Latreille in his *Familles du Règne Animal*, p. 322. Although we did not allude to this class in our exposition above referred to (art. Animal Kingdom), we think that the removal of the two genera just named from the Insecta is advisable, as it leaves the latter in a state to be more clearly defined, as well as actually composed of more natural constituent parts, or, as MM. Audouin and Milne Edwards have expressed it, *plus homogène*. "En effet," say these authors, "tous les animaux qui la composent alors ont le corps divisé en trois parties distinctes, une *tête*, un *thorax*, et un *abdomen*; trois paires de pattes sont fixées au thorax; souvent deux ou quatre ailes sont suspendues à la même partie; la tête porte deux *antennes* et deux yeux immobiles; la bouche est garnie d'une serie d'appendices modifiés pour broyer les alimens solides, ou pour pomper ceux qui sont liquides; un système particulier de vaisseaux sert à la respiration, et porte le nom de *trachées*; il existe un vaisseau dorsal qui n'est autre chose qu'un cœur rudimentaire; mais il n'y a point de véritable système circulatoire; les sexes sont distinctes; enfin, la plupart de ces êtres éprouvent, pendant les premiers temps de leur vie, des métamorphoses plus ou moins complètes; mais jamais ils n'acquièrent, après leur sortie de l'œuf, de nouveaux segmens à leur corps." (*Résumé d'Entomologie*, p. 12.) All true insects, then, are *hexapod*, or *six-footed*; and the few genera now or lately classed with them, but of which the amount of feet is greater than six, belong to the Myriapoda,—under which term the reader, in due time, will find their history and classification.

Definition.

however, present fewer nervures, and are not reticulated, as in the preceding order. The mouth is furnished with mandibles and maxillæ, and the abdomen of the female is terminated either by an ovipositor · or sting. Plates CCXXXI–II.

6. Lepidoptera (from λεπις, *a scale*, and πτερα, *wings*), containing all butterflies and moths, and generally characterized by the farinaceous or scaly aspect of the organs of flight, and the tubular or thread-like extension of the parts of the mouth. Plates CCXXXIII–VII.

7. Strepsiptera (from στρεψις, *a turning* or *twisting*, and πτερα, *wings*), including a few peculiar and parasitical species belonging to the genera stylops and xenos. This order corresponds to the *Rhipiptera* of Latreille, but we adopt Mr Kirby's denomination, as possessing a prior claim. Plate CCXXXI.

8. Diptera (from δίς, *twice* or *double*, and πτερα, *wings*), including the house fly, and other two-winged kinds. The mouth is furnished with a proboscis, and there are two organs called poisers or balancers (*halteres*) placed behind the true wings, one on each side. Plate CCXXXVIII.

9. Suctoria (so designated from their sucking propensities) is constituted by the genus *Pulex* of Linnæus, and differs from the ensuing apterous orders in undergoing a regular metamorphosis, and possessing what some regard as the rudiments of elytra.[1] Plate CCXXXIX. fig. 13, 13 *a*, 14, 14 *a*, 14 *b*.

10. Thysanoura (probably from θιαζω, *to dance*, and ουρα, *tail*),[2] likewise an apterous order, including the *Poduræ* and other tribes. Plate CCXXXIX. fig. 7, 8, 12, and 12 *a*.

11. Parasita (so named from their parasitical or adhesive propensities, because they dwell on the bodies of other animals) contains the genus *Pediculus* of Linnæus, and the *Nirmi* or bird-lice.[3] Plate CCXXXIX. fig. 10, 11, and 11 *a*.

The study of the structure and habits of this numerous and diversified class of beings has long been a favourite occupation with men of science in all the continental countries of Europe, and has assumed of late years in the southern parts of our own island a character of considerable and increasing importance. Works have been recently published in this country which need fear no comparison with the most finished examples of pictorial representation; and when we consider how sparingly the subject of Entomology has been hitherto patronized by the public, we cannot sufficiently esteem the exertions of those who have thus devoted their time and talents to a pursuit which brings with it no other reward than the delight which every instructed mind necessarily draws from the contemplation of a favourite subject. Entomology, in truth, still stands in a difficult and somewhat dubious position, and presents itself to many under a far less inviting aspect than its beautiful sister-science of Botany. In connection with the latter study, the very mass of mankind, even the *profanum vulgus*, however ignorant of the technical details, have many early formed, and therefore pleasing associations. Every country-house has its flower parterres, and numerous cottages their glowing borders,—botanic gardens have been formed in the vicinity of most of the larger cities, while nursery grounds are frequent in the neighbourhood even of provincial towns, —to say nothing of the "flower enamelled meads" which each sparkling spring and gorgeous summer calls into fleeting but constantly renewed existence. In addition to the more attainable nature of this popular pursuit, some botanical knowledge is also regarded as a requisite branch of medical education; and although a tin box and a microscope do not constitute a man of science, still the subject derives advantage from that general though it may be superficial culture. But in Entomology every thing exists in a different order of relation. No "trivial fond regards" come in aid of the impaler of insects; and even the creatures themselves are too often regarded with such abhorrence, that one feels the more inclined to admire how those who endeavour to hand them down to an ungrateful posterity, should themselves be accused of cruelty.

The time however is surely gone by when an apologetical defence of the study might be required, or in which the works of Omnipotence were regarded as important in proportion either to their magnitude or immediate subservience to the human race;—and although we desire not to fall into an opposite error by maintaining the greater beauty and excellence of the more minutely elaborated designs of the Creator, we yet feel that they are fully more calculated to awaken our wonder and admiration. It would be easy to say that the richest and most elegant apparel which adorns the human race is the product of a caterpillar; that the blistering medicines so essential to the practice of the sanitory art are compounded from a beetle; that honey and wax, so valuable as articles of domestic economy, are derived from the glad labours of a hymenopterous fly; and that even that splendid and regal dye the "Tyrian purple" of ancient days, supposed to have been obtained from the *Purpura patula*, a shell-fish of the Mediterranean, is superseded by the tinctorial uses of the cochineal, a small and obscure insect, which nevertheless the skill of the chemist has rendered indispensable even to the garment of kings. But in truth far higher and more delightful results ensue from these researches, than can ever be named in the "cui bono" catalogue of a mere economist; for whatever tends to elevate the mind of youth above the grosser pleasures of sense, or even occasionally to disconnect our maturer years from the more turbulent occupations and harassing cares which life is heir to, assuredly carries along with it its own reward. We doubt not that a more sedulous and frequent attention to natural history would in active minds pre-occupy the place which is otherwise in after years too often devoted to more perilous courses. Even the pursuits of literature are often vague and objectless, and not unfrequently engender a sickly sentimentalism, or other morbid affection in nowise akin to genius. But the objects which attract the attention of the naturalist are not the melancholy creations of the human intellect, which present so often but a lurid brightness, or a dim eclipse, in which noble thoughts are obscured by the "darkening scales" of vice or folly. They are the work of Him who cannot err, and who has doubtless not only peopled the teeming earth and the translucent waters of the "great deep" with all their innumerable and varied wonders, for a wise and beneficent purpose, of which our instruction and amusement form at least a portion, but has, by the implantation of that strong instinctive love of nature which all ingenuous minds possess, demonstrated his desire that we should ennoble our humanity by magnifying his manifold works, the "wondrous works of him that is perfect in knowledge."

While the beautiful simplicity and regular order observable in those phenomena which proceed under the superintendence of omnipotence, commonly called the operations

External Anatomy.

of nature, are well adapted to the comprehension of understandings laying no claim to the highest order, the more complex relations of the subject present a vast field for speculative or theoretical exercise, sufficient to occupy the faculties of the most powerful minds. It is thus that, in its totality, the subject of natural history holds out to each capacity the allurement of an occupation suited to every gradation of intellectual power; for while in its mysterious interconnection with other branches of natural science, as well as in its own peculiar complexities, it cannot be effectively grasped by mere human understanding, its manifold minor features may be scanned with intelligence by whoever desires so to do.

If indeed the value of a pursuit is to be estimated by the comparative ease with which it may be followed by persons of the most moderate fortunes, few can rank higher than Entomology. While the specimens sought for by the mineralogist and student of geology are frequently heavy and cumbrous, and not seldom extremely expensive, and while that sad representative of the beauties of the living Flora, called a *Hortus Siccus*, is but a frail and fleeting memorial of the "days of other years," presenting, even after a tedious and troublesome process of preservation (by courtesy so called), no trace of their original brightness, the most exquisite examples of entomological beauty, if not too roughly handled at the period of their capture, remain, with the most ordinary attention, for a lifetime in their pristine state,—and what that state actually is, all may satisfy themselves in the course even of the most superficial examination,—

> ....For nature here
> Wantons as in her prime, and plays at will
> Her virgin fancies.

Exceeding in amount of species all the other subjects of zoology,—unrivalled in the dazzling brilliancy of their colours, which combine the clearness and decision of tint possessed by flowers, with the exquisitely varied markings of the feathered race, and the metallic splendour of the mineral kingdom,—surpassed by no other work of creation in the wonderful structure of their parts, and certainly surpassing all in the adaptation of that structure to the perfect fulfilment of those natural though to us still mysterious instincts, which in every age have excited the admiration of mankind,—is it to be wondered at that the study of insects should occupy a prominent place in our pursuit of knowledge? Much more do we wonder that thousands of the best educated, and in other respects most enlightened minds, should still feel averse to a study which unfolds such a world of unseen wonders.

The subject, too, is literally inexhaustible; and while some who love to methodize, and thereby to circumscribe, the subjects of human knowledge, or who err in their estimate of the perceptive powers of the human mind as applied to other matters of enquiry, may be deterred by the vague boundaries of such a field, a greater number, and with more propriety it is hoped, may be induced to enter it, from the very consideration of such a rich and unreaped harvest. While a fragment of inert matter, which chemical analysis determines to differ in its constituent proportions from other fragments previously examined, is once in a lustre dignified by the name of a new *species*, and the name of a Haüy or a Dolomieu is bestowed on the unconscious mass,—and while, even in the richer domain of British botany, the student of that science, however much he may extend our knowledge of the localities of plants, labours with but a feeble chance of adding to the actual list even of indigenous species, and has probably no chance at all of ever refreshing his eyes with the sight of a plant which nobody ever saw before,—it is far otherwise with the innumerable tribes of insect life. The "gilded summer flies" are numerous as leaves in Vallumbrosa. No recess of the forest so obscure but there the "winged messengers" are seen to sport and play; and each summer sunbeam falls not alone on the dewy herbage of the open glades, but lights up the gorgeous hues of those bright creatures which a mystical philosophy has ennobled as the types of the disencumbered human soul, and which even the sombre Dante has named *angelical*.

> Non v'accorgete voi, che noi siam vermi
> Nati a formar l'angelica farfalla.

Every pool of water is pregnant with life; each lonely moor or old deserted quarry, which scarcely "feels in its barrenness one touch of spring," is the chosen abode of thousands of living creatures, of small dimensions it is true, but of singular beauty both of form and structure, and often adorned with hues,

> Which make the rose's blush of beauty pale,
> And dim the rich geranium's scarlet blaze.

Even the pastoral melancholy of the green mountains is enlivened by the occurrence of many interesting species. One of the most beautiful of European coleopterous insects (*Carabus nitens*) occurs among the peat *hags*, and other places where heath and turf abound, and where its sparkling coat of gold and green, tinged with a brighter lustre than that of rubies, is singularly contrasted with the blackness of the soil in which it seems imbedded. The desolate and cloud-piercing summits of the highest hills produce several species, which are the more highly prized from their scarcity, and the difficulties with which they are obtained.[1]

We have alluded to the ease and *economy* with which the study of Entomology may be pursued, more especially when our attention is confined to the species of a district. Of course the collector of foreign insects labours under some disadvantage, from the more multifarious nature of his subjects, their larger size, higher price, and more scattered localities. But the home collector, especially of the Coleoptera, is more favourably situated.[2] The total Entomology of most districts may be amply illustrated within the bounds of a cabinet of a few feet square, and the most ordinary attention and regularity suffice for its preservation. Most districts produce species which are comparatively rare in other quarters, and thus by means of interchanges numerous additions may be made from time to time: so that with a moderate share of assiduity and perseverance, a large collection may be amassed with little or no pecuniary outlay. In these and many other pleasant particulars, on which we need not here dilate, Entomology possesses advantages over all the kindred branches of natural history. We shall now pass to a short exposition of some of the more characteristic features in the structure and functions of insects.

CHAPTER II.

THE EXTERNAL ANATOMY OF INSECTS.

Our knowledge of the manners of these creatures presents us with few general results, and this is scarcely to be wondered at, when we consider with how small a number we have any accurate acquaintance. It may even be doubted whether we are completely informed of the history of any one species within the entire range of Entomology. Of some we know the perfect state, but have never seen the larva; of others the larvæ are well known, but the perfect insect remains in obscurity, so that when we consider the numerous changes which these creatures undergo, from their first hatching to their final metamorphosis, we need scarcely wonder that even the most familiar species present points in their history, which it is by no means easy to unravel.

---

[1] The foregoing brief "defence of insects" coincides with that which, since the above was written, has appeared in our *Entomologia Edinensis*.

[2] A glazed frame or drawer, lined with cork, and capable of containing many hundred species, may be made for a few shillings.

It is otherwise however with the classification of insects, which, depending mainly on an attentive examination of external characters, is so far independent alike of anatomical investigation and the study of manners, although these, when ascertained, form of course the truest test by which to appreciate the difference between a natural and an artificial system.

The period is comparatively recent during which the internal structure of insects began to be regarded as a subject of interest. Their external characters were the first to attract attention; and as a communicable knowledge of these was necessary for all the practical purposes of classification, as well as to establish the means of mutual understanding among naturalists, it is well that that branch has been rendered so complete and satisfactory. In former times, whatever facts of interest might have been ascertained, were too often but of slight avail, in consequence of our vague knowledge of the species to which they applied. But the most ordinary attention on the part of the anatomist, to the systematic works of modern times, will now suffice to inform him of the place which his subject occupies in the scale of nature; and hence the importance, not seldom overlooked by the physiologist, of even the minutest external characters, when accurately ascertained and clearly described. It has indeed been stated as a truism, that whoever attempts to deduce the real affinities of the animal kingdom from a consideration of the external characters alone, will in most cases mislead both himself and others.[1] But it must also be admitted, that comparative anatomists have too frequently an idea that nothing is or can be of importance which extends beyond the sphere of their own exertions. They forget that the general form and covering, and, in short, the whole of the external characters, however they may labour under the misfortune of being obvious to a common observer, are just as much a part of an animal's organic constitution, as the nerves, viscera, muscles, blood-vessels, and bones, or whatever else is most mysterious and recondite; and that, in fact, without a precise knowledge of the former, the information conveyed by the latter would be uncertain, or of no avail. The chief advantage of the internal structure is, that it is less liable to variation from the influence of local or accidental circumstances: its chief disadvantage results from the difficulty of its ascertainment, and the contrariety of opinion which exists among physiologists regarding the uses of the organs, even after their conformation has been ascertained. A mere knowledge of external character is perhaps nearly as useful as an acquaintance, however intimate, with anatomical structure, when nothing is either known or sought for respecting the external appearance, as a necessary guide to the higher knowledge of animal instincts and modes of life, the uses of living creatures in the general economy of nature, their exquisite adaptation to the circumstances under which they are placed, their distribution over the earth's surface, and other points of philosophical investigation. The mere anatomist may smile at the mere collector of shells and butterflies; and with just as much propriety may the mere naturalist or virtuoso smile in return at him who, knowing, or supposing that he knows, every convolution of a viscus, or ramification of an artery, is yet unable to recognise, amid the perplexingly multiplied varieties which may be presented to him, the precise animal which has been the subject of so much anxious and careful investigation. But when anatomy and natural history go hand in hand, the obscure labyrinth of nature, so far as human capacity can penetrate, receives its noblest illumination.

Notwithstanding the meritorious labours of Swammerdam, Malpighi, Réaumur, and Lyonnet, who were the first greatly to signalise themselves in the difficult field of insect anatomy; in spite of the more recent and scarcely less successful exertions of Cuvier, Comparetti, Ramdohr, Treviranus, Gaede, Sprengel, Savigny, Marcel de Serres, Geoffroy St Hilaire, Carus, Meckel, Audouin, and Dufour (to make no mention of many others who yet deserve to be held in remembrance),—such is the immense extent and variety of this wonderful class of beings, that we fall infinitely short of possessing any thing like a general or completed knowledge of their structure. In this paucity of well-established facts under which we labour, it would indeed be unphilosophical to attempt the induction of general rules; and all that we shall here attempt shall be to record such observations as seem likely to bear substantially upon the subject, and to have formed an actual advance in our knowledge of the anatomy and physiology of insects.

The study of the interior structure of these creatures does not at first sight hold out the promise of much that is either interesting or useful. The enormous distance which seems to separate all invertebrated animals from man, and even from the lower mammiferous and other vertebrated tribes, has induced the belief that no practical results can ever spring from such a source. But the philosophical observer, who knows how important is frequently the connection between the greatest and the least of things, and how, like the thread of Ariadne, the tracing of a slender chain may lead to unforeseen conclusions of the highest value, will not despise the lights which a better knowledge even of insect anatomy may be one day destined to throw upon some of the many still obscure points in the physiology of man. The observations of M. Dufour and others have already shown us what an admirable simplicity presides in these despised tribes over the exercise of those most important functions, which in red-blooded animals require such a complicated organic structure as to be almost incomprehensible. But as we descend in the scale of nature, we see more clearly the distinction between what is necessary, or merely accessory or superfluous, and thus by degrees we may attain to a knowledge of the essential characters of things.

Even in its more superficial bearings on natural history, the dissection of insects is necessary to ascertain several disputed points regarding the sexual distinctions of species, and to verify our views of the structure of the organs of the mouth, the antennæ, tarsi, and other external parts, on which our establishment of tribes and genera mainly depends. When it is desired to dissect an insect, it ought to be placed on a piece of cork, immersed in pure water; and the various parts, as they float in the liquid, may be fixed in their most appropriate position by means of needles. With a view to prevent deception from any alteration in the relative position of the internal organs, it is desirable to fix the insect in its natural horizontal posture, and to commence the dissection from the dorsal region downwards.

---

[1] Wilson's *Illustrations of Zoology*, vol. i. pref. p. 4.

The following observations on the dissection of the minuter animals may be of service to the student. "The first thing that I have to observe is, that all dissections of small and soft objects, *e. g.* worms, zoophytes, insects, mollusca, &c. where it is desirable to obtain even tolerably accurate results, should be performed *under water*, by which the parts are kept floating and separated from each other, and consequently present themselves more distinctly. A very simple contrivance for investigations of this kind may be prepared in the following manner: A mass of tough wax (not too soft) is to be laid upon one or more porcelain saucers or capsules of different sizes, which are then to be put in a warm place until the wax melts so as to cover the surface evenly to the depth of a half or a third of an inch. If the object to be examined be laid upon this surface, it may be fixed by needles in any position that is wished; and, when covered with clear water, developed and dissected by means of suitable instruments. Of these, the best are very delicate forceps; pointed, well made, sharp-cutting scissars; and small knives like cataract needles, some round, others with cutting edges, and fixed in slender wooden handles. For separating parts I have also employed small horn probes and fine brushes; whilst for examining them a good magnifying glass is frequently indispensable. If it is wished to preserve a preparation thus made, wax coloured at pleasure, as for the purpose of injections, is to be formed into little tablets about a quarter of an inch thick; one of them is then to be placed upon the saucer or capsule containing the preparation; the latter may then be transferred to it, arranged suitably upon it, fixed there by means of short needles, and both together placed in alcohol. Nor must I forget to mention, that the examination of very delicate organizations may frequently be conducted with greater facility and accuracy, if the object be previously allowed to remain some time in spirit, and thereby to become harder and contracted. This applies particularly to the dissection of nervous organs, and to the examination of very small embryos, of mollusca, and worms. There are various ways of destroying worms, insects, &c. for the purpose of dissecting, without injuring their organization. Mollusca, snails for example, as Swammerdam has remarked, are to be allowed to die in water, because by that means their body swells, and all the parts become more distinctly visible; they may afterwards be kept in spirit (though not too long) for dissection. Worms, the larger zoophytes (for the smaller must be examined whilst alive), caterpillars, &c. are best destroyed by means of spirit; insects, on the contrary, by being dipped rapidly in boiling water, or in oil of turpentine."[1]

SECT. I.—THE EXTERNAL COVERING OF INSECTS.

Our knowledge of the structure and anatomy of this class may be said to be still in its infancy; for although many important facts have been legitimately generalized, we are still in ignorance of the formation of a thousand species for every one which has been examined. As the harder parts of insects, to which the muscles are attached, are superficial, the class has been described as bearing their skeletons externally; and a transcendental anatomy has not scrupled to determine the exact analogy which each portion of their covering bears to the bony frame-work of the vertebrated tribes. This comparison has been instituted by M. Geoffroy St Hilaire, an eminent physiological naturalist of France, who maintains, with many of his countrymen, that all animals are vertebrated. The doctrine, whatever may be its other merits, is not entitled to the credit of novelty, as an English writer of the name of Willis had, so far back as the year 1692, published his opinion that the external envelope of the body of insects represented the internal articulated column of the vertebrated tribes. M. de Blainville, on the other hand, regards the corneous covering of insects rather as analogous to the skin or cutaneous system of the higher classes.

The hardness of the calcareous or horny envelope of the greater number of insects is owing, in Latreille's opinion, to the consistence of the excretion interposed between the dermis and the epidermis, or what is termed in man the *mucous tissue*. This excretion also contains the brilliant and varied colours which add so greatly to the beauty of the class.[2] According to M. Odier, who has attentively examined the composition of the harder parts of insects, the substance of this envelope is of a peculiar nature. He has named it *chitine*. He observes that the phosphate of lime forms the great proportion of all the salts contained in the teguments of insects, while that ingredient is but trifling in the covering of the Crustacea, although the latter abounds in the carbonate, which is not found in the other class.[3] The facts stated by him militate against the analogies attempted to be established on the subject; and the observations of M. Straus go far to demonstrate that those teguments do not form a true skeleton, but really represent the skin of the vertebrated classes. When we use the word skeleton, then, in relation to insects, the reader will understand its application merely to the external covering.

On analysing the elytra of the cockchafer, M. Odier ascertained the existence, 1*st*, of albumen; 2*d*, of an extractive matter, soluble in water; 3*d*, of a brown-coloured animal substance, soluble in potass and insoluble in alcohol; 4*th*, of a coloured oil, soluble in alcohol; 5*th*, of three salts, viz. subcarbonate of potass, phosphate of lime, and phosphate of iron; 6*th*, of a peculiar substance which constitutes a fourth part in weight of the elytron. Albumen is so generally distributed among the animal organs that its presence was to be expected. But the oil is deserving of further experimental observation. Robiquet found it of a green colour in cantharides; while, according to Odier, it is brown in the cockchafer, and red in a species of crioceris. Now as each of these insects is itself of a corresponding hue, it is natural to suppose that the oil is the colouring matter. The peculiar substance which forms so large a proportion of the elytra is named *chitine* by M. Odier. If we plunge a coleopterous insect into a solution of potassium, and keep up a pretty high temperature, we shall observe that the so-called skeleton neither dissolves nor changes its form; it merely becomes discoloured during the operation, while all the viscera and interior muscles disappear; and whatever remains of the insect is *chitine*. This substance exists in the whole of the envelope, and is also found to occur in the more solid covering of the Crustacea.

If however we compare the preceding results with those obtained by M. Chevreul in the course of his experiments on crustaceous animals, we shall perceive some remarkable distinctions in the constitution of their harder parts. The presence of subcarbonate of potass is a striking character among insects. It does not occur in the class Crustacea. The phosphate of lime, a sparing ingredient among the latter, forms a preponderating part of the salts in the envelope of insects, while the carbonate of lime is absent, although it forms the base of the carapace or covering of crabs and lobsters. It has been stated as a regulating law in animal chemistry, that the bones of the higher orders have more of the phosphate and less of the carbonate of lime in their composition, while the proportions were reversed among the inferior tribes. But the observations of M. Odier show the inadequacy of chemical character to serve as a basis on which to found our analogies of organization; for if strictly applied to insects, that class must be removed from the place which they now occupy in our system, and be combined with others of a higher nature, with which in truth they have no connection.

---

[1] Carus's *Introduction to Comparative Anatomy*, translated by Gore, vol. ii. p. 389.

[2] *Règne Animal*, t. iv. p. 2.

[3] *Mem. de la Soc. d'Hist. Nat.* t. i. p. 29.

The harder and more solid parts of insects are certainly to them what the internal skeleton is to the vertebrated tribes. They form the support and frame-work of the body. It is on this account that the term *skeleton*, though not strictly applicable, has been used, both in ancient and modern times, to designate the *corneous external system* of these creatures. This comparatively solid system is itself formed by the union of many parts, which however have received no general name; so that, while in discussing the vertebrated tribes we merely say that their skeleton is formed of bone, all that we advance in regard to insects is, that it is composed of pieces. In the higher tribes each individual bone is well known by its own distinctive name; but the insect tribes in that respect have been but obscurely defined. Guided by the light of human anatomy, observers have sought to discover in insects all those parts to which they could apply previously established names; but analogies based upon mere appearance are incapable of great or useful extension; and insects would certainly have been better known had they been studied in the first place individually, and no far-fetched comparisons instituted till after a more ample knowledge of actual organization. But instead of this, the best determined functions of the superior animals have been assumed as points of departure, and all the parts of insects which *seemed* to fulfil the same purposes have been determinately regarded as analogous. Now it is quite admissible to say, that in insects, as among the vertebrated tribes, there is progression, vision, manducation, &c. because these are the attributes, more or less general, of all living beings; but it has not always been demonstrated that particular and more special functions are always performed by the same or apparently corresponding parts. M. Dufour, however, has announced the following results in relation to the articulated animals themselves: 1*st*, that the skeleton of the Crustacea and Arachnides (two important classes already described in this work) does not differ from that of insects except by the mode of growth of the rings of which it is composed; 2*d*, that those two classes of animals and insects themselves do not differ among each other, but by the greater or less extent in the development of the parts of which they are composed.

The same may be asserted in regard to the disparities observable between the different conditions of insects in the larva, the chrysalis, and the perfect state. The various forms under which the same species is exhibited, and the singular and sometimes sudden transformations to which it is subjected, are found to result, when analysed, from the growth of parts. This has been demonstrated by the writings of Swammerdam and other modern writers on the anatomy of caterpillars, as well as by the beautiful and more recent observations of Savigny on the mouths of Lepidoptera in the perfect state, compared with the same parts in their earliest condition.[1] The observation is particularly applicable to the solid parts of insects. In the larva each segment exists under a nearly uniform development, while in the perfect state several of these segments have acquired a prodigious increase. This is the cause of the vast difference in their exterior envelope at different periods of their existence. The nymph or chrysalis is in the intermediate condition, and is formed, like the larva, of simple rings, which, however, no longer exhibit an equal degree of uniformity. But the perfect insect is the final term of transformation. Considered in a general way, its covering does not essentially differ from that of the larva; but the three segments next the head have acquired a great increase of bulk, to enable them to support the appendages of legs and wings, which were merely rudimentary, or scarcely existent, in its first condition; and the distinction of head, thorax, and abdomen becoming strongly visible, the entire aspect of the insect has undergone a change.

It is highly interesting to observe the influence which the decrease or development of one portion of structure exercises upon another; in other words, the constant and intimate relation of the proportion of parts. The maximum of increase in the metathorax is always in relation to the rudimentary state of the mesothorax, while, on the contrary, the development of the latter produces or accompanies the decrease of the former. Thus also the parts of the mouth, as demonstrated by M. Savigny, are sometimes free, and capable of varied movement, for the purposes of mastication; while in several tribes they are brought close together, lengthened, and as it were amalgamated in the form of trunk or sucker; and so the segments of the thorax, in the different orders, more or less disunited among themselves, support the wings, the balancers, the elytra, according to the various kinds. From these and similar considerations have been deduced the conclusion that the increase of one portion exercises over the neighbouring portions a peculiar influence, which explains whatever differences may be remarked in the individuals of each order, family, and genus. And this general consequence, which results from numerous observations, necessarily includes and accounts for that incoherent series of anomalies so puzzling to the superficial inquirer, but which are only regarded as such, because the labourers in the field of anatomy have but seldom taken into their consideration the totality of the articulated animals, and have more seldom still thought fit to occupy themselves in a careful comparative analysis of the parts which enter into the composition of the external skeleton of these despised tribes.

We shall here briefly consider the essential characters of the so-called skeleton among the articulated tribes. It is composed of segments, which are themselves formed by a determinate number of pieces; but their most obvious character is, that they are provided with a pair of feet, and with two openings to the respiratory organs. But along with such segments as present these parts, we may usually observe many others which are not so provided, or at least in which the feet are wanting; and they may either differ in their size and proportions, or closely resemble each other in those respects. In the latter case, the most simple form is exhibited; and if we ascertain the composition of a single segment, and their amount, we have a knowledge of the entire animal. This simplicity of form, however, is not often observable; for it more frequently happens that the same individual presents great disparity in the size and composition of its segments, and in the appendages with which they are furnished.

The Scolopendræ (belonging to the class MYRIAPODA) ex-

---

[1] *Mémoires sur les Animaux sans Vertèbres.*

hibit, according to M. Dufour, one of the most simple forms of the articulated classes, in as far as they present the greatest uniformity of character in the parts of which they are composed. Even in them, however, we may observe, at the anterior portion, some pairs of feet, which are rudimentary, and crowded together towards the head; so that it would be possible to figure an animal still more uniformly composed, by supposing that the feet thus thrown together had been developed uniformly with the appendages of the ensuing segments. We should then have had to recognise merely a head, and a certain number of rings, all of a like nature. But it might be possible still further to reduce and simplify the proposition, by regarding the head itself as an assemblage or union of segments, bearing appendages merely analogous to the feet. Thus, to realize the supposition of a skeleton uniformly constructed throughout all its parts, nothing more would be necessary than to give to the segments of the head a development equal to that of the others, and to restore to its appendages (the feet) their essential usage, that of locomotion, instead of the secondary usage to which they had been subjected. This view has been presented in order to exhibit what has been regarded as the fundamental plan of insect formation; for it is in truth the corresponding or unequal increase of the segments, the union or division of the pieces of which they are composed, the maximum of development in some, the rudimentary condition of others, that form the agreements or differences of character in the entire series of articulated animals.[1] If the development is uniform, or nearly so, in each segment, we have the condition of the *Annelides*, of *worms*, and of the *larvæ* of insects. If, on the contrary, this equilibrium is destroyed, and the maximum of increase takes place in the first, second, and third segments ensuing the head, we have the form and character of a *perfect insect*; if the change is still greater, we reach the *Arachnides*; if greater still, the *decapodous Crustacea*.

The importance of studying the skeleton of insects is greater than even among the higher classes, because, being essential, it forms a genuine basis, and being at the same time external, it offers to the eye of the zoologist a ready mode of determination.

While engaged in the consideration of the various organs of insects, a numerous list of disparities in structure might no doubt be collected, and the term *anomaly*, according to its frequent but by no means philosophical application, brought into constant use. That fatal word, however, has been too often substituted in place of an explicit interpretation of phenomena not in any way difficult of solution, certain general principles being kept in view. Of these, one of the most importance is, that all the differences exhibited by insects, and all the so-called anomalous organs which they present, are the result of a greater or less development of certain parts existing generally throughout the entire class.[2] The contrariety of opinion among naturalists regarding the existence or proportion of certain parts of structure, has arisen partly from a discordance in the use of terms, and partly from the organs themselves not being submitted to a careful analytical investigation. It is thus, for example, that the names of *sternum* and *scutellum*, in place of being bestowed on portions of which the contours have been precisely determined, have only been applied when these portions happened to exhibit certain accidental and conventional characters. By this means we read in almost every page of classification, that one insect possesses a scutellum and that another does not; or that a particular genus is characterized by its existence, and another by its absence; while the fact is, that these parts exist in all insects, although the names in their usual application have been bestowed only upon peculiar and not very important variations in the *form*.

SECT. II.—THE EXTERNAL CHARACTERS OF THE PRINCIPAL SEGMENTS OF AN INSECT'S BODY, VIZ. THE HEAD, THORAX, AND ABDOMEN.

The form of the external covering of insects, even of the same species, differs greatly according to the existing condition of the individual. The segments of which the bodies of larvæ are composed are generally of a uniform size when compared with each other, and the singular phenomena presented by metamorphosis consist chiefly in the greater development assumed by certain segments than by others. The nymph (called chrysalis among the Lepidoptera) exhibits the intermediate or transitionary state. Its segments are unequally developed, and this inequality is greatly increased on the assumption of the final state, in which certain segments are prodigiously enlarged, while others suffer a corresponding diminution. In the imago, or complete condition, the three segments next the head undergo the most notable alteration; for, besides their increase of bulk, they become furnished with wings and articulated legs, which had previously existed in a very rudimentary condition. In that state also the relative proportions of the segments are so changed that the identity of several becomes difficult to recognise, and the most obvious divisions henceforth consist of *head*, *thorax*, and *abdomen*. These parts are severally characterized by peculiar attributes, the nature of which we shall now endeavour to explain.

The *head* is by far the most complicated portion, and it is necessary that its structure should be well understood, as it furnishes the most important characters on which modern genera are founded or made known. The parts most deserving of attention are the *mouth*, *antennæ*, and *eyes*.

The organs of the mouth present in their different combinations a great variety of form among the articulated classes. In relation to all such animals as are provided with a head, more particularly the vertebrated tribes, the term mouth is never of ambiguous application, but refers to those parts which are placed exteriorly at the entrance of the intestinal canal, and effect the process of mastication; but in regard to the acephalous or nearly headless tribes, such as annelides, worms, and the radiated animals, its application is less definite and precise. Among the great series of living beings included by Linnæus in the class of insects, all of which are furnished with a head, the parts of the mouth are no longer doubtful. It has been remarked, however, that the sucker of the larvæ in the last family of the dipterous order being entirely interior when not in use, presents a singular approximation in that particular to the intestinal worms.

It will be readily conceived that the mouth of insects must be adapted to the particular manners of life peculiar to each natural group, and must therefore vary in accordance with their instinctive habits. It was thus that even the earliest naturalists perceived and expressed the distinction between insects provided with teeth or cutting jaws, and those furnished with trunks or suckers. The use of the microscope in modern times, and the deep desire which prevailed towards the conclusion of the seventeenth and commencement of the eighteenth centuries, to illustrate the mysteries of animal organization, produced much more detailed and exact accounts of the parts of the mouth in insects than were previously possessed. The works of Leeuwen-

External Anatomy.

hoeck, Swammerdam, and Réaumur are mines of information; while Scopoli and Degeer still further generalized the observations of these illustrious naturalists. Scopoli, we believe, was the first to apply the knowledge of these parts in characterizing the genera of the hymenopterous and dipterous orders; but it is to a celebrated disciple of Linnæus, John Christian Fabricius, that we owe the first general theory of the parts of manducation, and its application to entomology in general.

The alimentary substances sought for by insects are either comparatively hard and solid, or of a more soft and fluid nature. Thence we find upon examination numerous tribes of insects provided with a mouth so constructed as to tear and masticate the substances on which it is designed to act; while many others are characterized by a tube-like mouth, or one resembling a delicate tongue extended when in action, and spirally rolled upon itself when in repose. Hence the great primary distinctions among the orders of insects, and their recognised division into masticators (*mandibulata*) and suckers (*haustellata*), the former living on solid substances, the latter on such as are fluid. Whatever may be the structure of the mouth in insects, it is to one or other of those types of form that each must be referred. We are indebted to the beautiful researches of Savigny (1814) for the first accurate analysis and elucidation of these parts, and of their relationship throughout the articulated tribes. Latreille, however, had previously instituted a slighter comparison between the mouths of the suctorial and mandibulated tribes, as Lamarck has admitted in his report on Savigny's work.

Savigny divides insects formerly so named into two groups, the *hexapodes*, or such as have six feet, and the *apiropodes*, or such as possess a greater number. The mouth of the latter forms two proper types distinct from those of the former; but it is with the polymorphous hexapodes, or such as undergo transformations, that is, insects properly so called, that we are now concerned. We shall first consider the parts of the mouth in the masticating tribes. They are essentially as follows: The *labrum*, the *mandibles*, the *maxillæ*, the *palpi*, the *labium*, and the *mentum*, the two latter, according to the views of different observers, sometimes passing under one and the same name. The reader may here consult Plate CCXX. fig. 1, *a, b, c, d.*[1]

The *labrum* or upper lip (fig. 1, *a*) is a flattened somewhat deflexed portion, consisting of a single piece,[2] placed on the upper side of or above the mouth, and capable of moving upwards and downwards, or vertically. It is variable in form, but is usually somewhat square, often wider than long, and frequently notched or bifid. It is of a horny consistence, sometimes coriaceous, or even approaching to what may be named membranous in certain tribes, and is attached to the anterior portion of the head by a very short articulation.

The mandibles or upper jaws (*mandibulæ*, fig. 1, *bb*) are two strong horny pieces, generally of a triangular form, more or less curved, convex externally, concave on their inner surfaces, and frequently toothed or serrated on their interior edge. They are placed on each side of the mouth by insertion on the sides of the head, immediately beneath the labrum or upper lip, which usually covers their base. They are each composed of a single piece of a hard consistence, and may be said to correspond to the jaws of the vertebrated tribes, the process of mastication being principally performed by them. They differ, however, in this respect, that their motion, instead of being vertical, is horizontal, or from within outwards, and *vice versa*. They vary greatly both in their actual size and relative dimensions, being small and slender in the glow-worm (*Lampyris*), and very large, projecting, and antler-like in the stag beetle (*Lucanus cervus*), the species which we have selected for our engraved illustration. These internal surfaces are frequently parallel, but their dentations are not always the same in each, the projections of the one being however frequently so arranged as to enter the concavities of the other in order to admit of their closer union. But this is not seldom prevented by the curvature of the tips; and in several instances, where the mouth is wide, and the mandibles rather remote from each other at the base, the blades cross each other a little beyond the centre. The dentations of the mandibles, though sometimes called teeth, are merely projecting parts, although in the orthopterous tribes a coriaceous lamina seems in some respect to distinguish them from the body of the mandible to which they are attached, thus exhibiting an approach to that mode of fixture called *gomphosis*, in which one bone is fixed within another, as in the teeth of the higher tribes. The mandibles are more variable in their forms than the maxillæ, and may occasionally be observed to differ (as in the genus *Lucanus*) even in the sexes of the same species.

Immediately beneath the mandibles are situated the *maxillæ* or under jaws (fig. 1, *cc*), which are likewise placed on each side of the mouth, and take their origin from the inferior and internal part of that cavity, near the origin of the under lip. Like that of the preceding parts, their action is horizontal, but their texture is less rigid, approaching to membranous, their colour usually paler, and their internal edges toothed, or finely fringed with hairs. The different portions of the maxillæ have received different names, such as the *cardo* or hinge, the *stipes* or stalk, and the *lobus* or lobe (one or more) which forms the terminal portion. The last named is the most important portion, as it acts upon the food when preparing for deglutition, and when armed with teeth its substance is as hard as that of the mandibles. "This part," says Mr Kirby, "is either simple, consisting only of *one* lobe, as you will find to be the case with the *Hymenoptera*, *Dynastidæ*, *Nemognatha*, and several other beetles; or it is compound, consisting of *two* lobes. In the former case, the lobe is sometimes very long, as in the bee tribes, and at others very short, as in hister, &c. The bilobed maxillæ present several different types of form. Nearest to those with one lobe are those whose lower lobe is attached longitudinally to the inner side of the stalk of the organ, above which it scarcely rises. Of this description is the maxilla in the common dung beetle (*Geotrupes stercorarius*), and rove beetle (*Staphylinus olens*). Another kind of formation is where the lower lobe is only a little shorter than the upper; this occurs in a kind of chafer (*Macraspis tetradactyla*, Macleay). A third is where the upper lobe covers the lower as a shield; as you will find in the *Orthoptera* order, and the *Libellulina*, and almost in *Meloe*. A fourth form is where the upper lobe somewhat resembles the galeate maxilla just named, but consists of two joints. This exists in *Staphylinidæ*, &c. The last kind I shall notice is when the upper lobe not only consists of two joints, but is cylindrical, and assumes the aspect of a feeler or palpus. This is the common character of almost all the predaceous beetles (*Entomophagi*, Latr.)."[3] This lobe, which has been usually regarded as an additional palpus or feeler, is strictly analogous, in Mr Kirby's opinion, to the upper lobe in other insects, and he thinks it ought rather to be called a palpiform lobe than a *palpus*. When there are two lobes, the upper one is most commonly the longer; but in many species of the tribe last alluded to, the lower equals or even exceeds the upper in length.[1]

---

[1] *a* is the labrum, surmounted by its broad nasus; *b* the mandibulæ; *c* the maxillæ, with their jointed palpi; *d* the bifid labium, with its two palpi and broad basal portion or mentum.

[2] In the female of a small bee of the genus *Halictus* it is said to be furnished with a slender appendage.

[3] *Introduc. to Entom.* vol. iv. p. 442.

Most of the predaceous beetles have the inner lobe of the maxillæ armed with a terminal claw, which, among the Cicindelidæ, is articulated and moveable, but fixed in the other carabideous kinds. The maxillæ are chiefly serviceable in holding the food, and preventing its falling from the mouth during the action of the mandibles, although in certain cases they no doubt also act their part in comminution. They are more fixed in their forms than the mandibles, and are of more essential service to the naturalist for the purposes of classification. Fabricius, indeed, has deduced the principal diagnostic of ten out of the thirteen orders (or classes, as he terms them), of which his system is composed, from these important parts.

We shall now briefly notice certain appendages of the maxillæ, the existence of which forms another distinction between them and the mandibles or upper jaws, which are never so provided. Towards the middle of the outer edge of the maxillæ are attached two slender articulated filiform processes, known under the name of palpi (see the figure above referred to); the longer pair being the external, the others the internal palpi. Both are called *maxillary*, to distinguish them from the *labial* palpi, afterwards mentioned. According to the view expressed by Mr Kirby in the preceding quotation, the reader will perceive that each maxilla may be regarded as properly possessing only one palpus, although in certain tribes the upper lobe being jointed and *palpiform*, has occasioned its being regarded as one of these organs. The palpi are distinctly articulated, or composed of several jointed parts, and are capable of rapid and extended motion. They derive their name from a Greek word, which signifies to feel, and are supposed to constitute one of the principal organs of touch. Their uses, however, in the insect economy have been variously interpreted. Bonsdorf regarded them as the organs of smell; while Knock, agreeing in that opinion so far as regards the *maxillary* palpi, conceives that those of the *labium* exercise the faculty of *taste*. Cuvier and Kirby favour touch as their true function, and this view is confirmed by the constant use which numerous species make of these organs while walking, by applying them perpetually to the surface of whatever objects they pass over. That they perform that function is rendered extremely probable by their structure, which is beautifully adapted, by its peculiar pliancy, to the examination of the substances with which they come in contact. They are in some respects analogous to the articulated extremities which form the principal seat of the sense of touch in vertebrated animals. It has also been noticed that several aquatic beetles, while swimming, bend back their antennæ, and stretch forward their palpi, as if to explore their way through the ambiguous and weedy waters. As accessory to the maxillæ, they are no doubt also employed in the selection of the most suitable alimentary portions of whatever substances have been previously seized upon by the more powerful parts of the mouth. In many insects there is only a single palpus to each of the maxillæ.

As the mouth is covered above by the *labrum*, or upper lip, so it is closed below by the under lip, or *labium* (fig. 1, *d*). The latter differs in its structure from the labrum, being more complex than that organ, and composed as it were of two portions joined together. It varies in its form, is usually notched in front, and frequently furnished with a triangular tooth in the centre, which is sometimes bifid. Mr Kirby defines the labium as a moveable organ, often biarticulate, which, terminating the surface anteriorly, covers the mouth from beneath, and is situate between the maxillæ. It includes the mentum and labial palpi. The more uncovered portion of the labium, or that which projects from the basal portion, is now named *languette* or *ligula* by Latreille, in consonance with the nomenclature of Fabricius. The *mentum*, or chin, is the lower joint of the labium when the latter is jointed; in other cases its base.

Some contrariety of opinion seems to exist in the nomenclature of these parts. Mr Macleay bestows the name of *mentum* on the middle piece of the lower apparatus of the mouth. Its anterior portion, to which the palpi are so frequently attached, he calls the *labium*, while the basal part of the mentum is designated the *stipes*. In this view the labium of Macleay corresponds to the *ligula*, or rather tongue, of Kirby, while the mentum of the latter is analogous to the stipes of the former; for it appears that the term mentum is only applied by the author of the *Introduction to Entomology* to the lower division of the labium, when that organ (as in *Hydrous piceus*) appears to consist of two joints or pieces. When there is no apparent division, or the only separation consists in a transverse elevated line (as in some lamellicorn beetles), or an obtuse angle formed by the meeting of the two parts, then the entire piece (the *mentum* merging in it) is regarded by Mr Kirby as the *labium*.

Among the greater proportion of masticating insects there is placed anteriorly at each side of the ligula a small supporting piece or article, which takes its rise a little above the pharynx, and is terminated by a projecting appendage. These parts were named *paraglossæ* by Illiger; and M. Latreille regards them as the true representatives of the tongue of the higher tribes. The labial palpi (Fig. 1, *d*), are inserted on each side of the ligula, and are usually longer than the internal and shorter than the external maxillary palpi. These palpi have never more than four articulations, in which they also differ from the external maxillary, which range from four to six. They are called labial palpi, because in many cases they derive their origin from the labium strictly so called; but in reference to Mr Kirby's nomenclature of the parts, they might with equal propriety be denominated lingual palpi, since they not unfrequently emerge from what that excellent observer considers as the tongue. Among the predaceous Coleoptera, indeed, their source seems common to both these parts, as their base on its upper side is attached to the labium, on its under to the ligula or tongue.

In some insects, such as the Orthoptera and dragon-flies, the membranous portion with which the anterior or internal face of the ligula is furnished, is thick and dilated near the centre, in the form of a little tongue, and is often divided near the middle by a groove. This portion, in the opinion of Latreille, probably occupies the place of the *paraglossæ*; for these latter, in the instances referred to, are wanting, or not to be recognised.

These are the principal parts of the mouth among the masticating insects. At the anterior root of the ligula, and a little lower than the middle of the interior space which intervenes between the mandibles, is placed the *pharynx*. In many Hymenoptera this orifice of the œsophagus opens and shuts by means of an appendage, previously noticed by Réaumur in humble bees, and taken by Latreille for the labrum, in his observations on the structure of wasps. Savigny has since paid particular attention to it, and has named it the *epipharynx* or *epiglossa*. Latreille conceives it would be more simple to call it the *sublabrum*, because it is inserted beneath the anterior and superior margin of the head, immediately after the origin of the labrum. It is formed of two flattened portions, entirely or in great part membranous, applied the one upon the other, and of a triangular form. The upper portion is the most advanced. This epipharynx, instead of being peculiar, as some have supposed, to the Hymenoptera, may be safely regarded as existing in the other masticating insects, particularly the Coleoptera, among which it seems represented under a modified form of structure by the membrane which clothes the corresponding portion of the head.

[1] *Introduc. to Entom.* vol. iv. p. 442.

Although the hymenopterous tribes differ from the other mandibulated orders, by the prolongation of the maxillæ and labium, and the valvular aspect of the former, yet the parts of the mouth do not present any essential distinction. A remarkable characteristic of these orders, however, consists, as Savigny informs us, in the absence of the mentum properly so called. They also exhibit this disagreement from the other masticators, in as far as their maxillæ embracing longitudinally the sides of the labium, these parts unite together so as to form a tubular body or trunk (*promuscis*), serving for suction. As their aliments consist of softish substances, or of nectarous juices, which, passing between the maxillæ and the labium, by means of the successive pressure of the former parts upon the latter, eventually arrive at the pharynx, they may in truth be regarded as semi-suctorial. Even the Rhinchophori among the Coleoptera, and the Panorpati in the neuropterous order, are furnished with an apparent trunk or prolongation of the muzzle (*prorostrum*); but that peculiarity is nothing more than an extension of the anterior portion of the head; and the organs of manducation, placed at its extremity, though of diminished size, in no way differ in structure from those of the other groups of their respective orders. We may add, that the labium or lower lip in the hymenopterous tribes is generally moveable at its base, as may be observed in the corresponding tribes of the suctorial insects.

In the suctorial or haustellated orders, properly so called, the organs of the mouth appear at first sight to differ entirely from those above described. The parts which are regarded as analogous to the maxillæ, and frequently even those which represent the mandibles, are fixed and immoveable, either entirely so, or towards their base, and (in regard to the maxillæ) as far as the origin of the palpi. When the terminal portion is moveable, it is long, narrow, linear, sometimes in the form of a thread or bristle, sometimes resembling a dart or lancet, and fitted for piercing. The pharynx is the central point around which these portions arrange themselves after the tubular form. Sometimes the lower lip, united with the inferior portion of the maxillæ, and fixed like it, closes the cavity of the mouth, and the maxillæ then constitute a kind of spiral tongue. In other cases it is greatly prolonged, and assumes the form of an articulated tube, or of an elbowed trunk, usually terminated by two lips susceptible of dilatation. In either of the latter states it serves as a sheath to certain portions of a scaly structure and piercing nature, in the form of a bristle or lancet, and representing the other parts of the mouth. Sometimes this sheath (as in *Pulex*) is bivalvular, but it more frequently consists of a single piece laterally folded so as to form a tube open on the upper surface. In this longitudinal canal or gutter, the preceding parts are lodged, and compose by their general union the sucker, or *haustellum*. In some instances the palpi have disappeared, in others only two are visible. When there are four of these parts, two of them, the maxillary, are extremely small, or almost imperceptible. Sometimes, as among the pupiparous Diptera, the lower lip is either nonexistent or rudimentary, and the palpi become the sheath of the sucker. Though we make frequent use of the latter term, it may be remembered that its application is not strictly correct, as it is not by suction, or the production of a vacuum, that the alimentary juices mount towards the pharynx, but rather by the continuous pressure of the parts upon each other.

Of all the suctorial or haustellated tribes the Lepidoptera are those which differ least from the type of the mandibulated orders in the structure of the mouth,—on which account they have been made to follow in a supposed natural sequence the hymenopterous insects.[1] Their mouth seems to consist of a labrum and of two extremely small mandibles; of a trunk spirally rolled, improperly regarded as a tongue, and presenting interiorly and throughout its entire length three canals, of which, however, the central alone serves for the influx of the alimentary juices, and formed of two linear or filiform bodies, surrounding the pharynx at their origin immediately beneath the labrum. They represent, under peculiar forms and proportions, the terminal parts of the maxillæ, united, hollowed into deep gutters on their internal side, and bearing each a palpus, usually very small and tuberculiform. There is also a labium or lower lip, of a nearly triangular form, immoveable, united, as formerly mentioned, to the inferior part of the maxillæ, which supports the filiform or trunk-like portion, and bearing two triarticulate palpi, covered with scales or hairs, and placed on each side of the trunk, for which they form a kind of sheath. The intermediate canal of the trunk is produced, according to the detailed description given by Réaumur, by the union of the gutters of the internal face of the filiform or extended portions.

The sucker of the hemipterous tribes received from Fabricius the name of *rostrum*, a term translated beak (*bec*) by Olivier and other entomologists of France. A blade more or less linear, coriaceous, divided into three or four articulations, rolled up at the edges so as to form a conical or cylindrical tube, always directed inferiorly while inactive, and presenting along the centre of its upper or anterior surface a kind of canal produced by the opening left between the rolled-up margins,—a sucker composed of four slender, capillary, corneous, flexible, and elastic threads, disposed in pairs, but combined together, with the two inferior portions united in one at a short distance from their origin,—a small piece in the form of a triangular ligula, usually toothed at the extremity, rather coriaceous or almost membranous than of a scaly texture, and covering from behind or from the sides of the tubular body the base of the sucker, and inclosed along with it in the groove of the general sheath,—another piece of the same consistence with the preceding, corresponding by its insertion, and the position which it occupies, to the labrum or upper lip, covering from above the base of the sucker, most frequently itself

---

[1] See Plate CCXX. Fig. 5 exhibits the structure of the mouth in *Papilio Machaon*; *a* the head viewed in front, exhibiting the round eyes, one turn of the spiral proboscis, with the pilose labial palpi on each side; *b* shows the tubular spiral maxillæ (which by their union form the proboscis), with the vestiges of palpi at their base; the circular apertures on each side at the bottom of the figure indicate the insertion of the labial palpi; *c* represents the cleft labium and the two palpi, the left one being deprived of its scales to show the articulations; *d* is the minute labrum, with the mandibles on each side of it, ciliated on their internal edge. Fig. 8 exhibits the mouth of another lepidopterous insect, the *Lyndia cannarum* of Savigny; *a* the eyes, scaly spiral proboscis, and the four palpi; *b* one of the maxillæ, with its palpus; *c* the labium and palpus; *d* the labrum and mandibulæ.

External Anatomy.

likewise inclosed in the sheath, and of a more or less elongated triangular form,—these are the parts which enter into the composition of the beak-like mouth or rostrum of the hemipterous tribes.[1] The single superior portion which Latreille regards as the analogue of the labrum, appears to cover, at least among the Cicadæ, the base of another more elongated and pointed portion, which has been viewed as corresponding to the epipharynx.[2] The other single and opposing portion, protecting from behind the origin of the sucker, and placed immediately behind the pharynx, represents, according to Savigny, the tongue or hypopharynx. The two superior filaments of the sucker, or those which are exterior, replace, or rather represent, the mandibles, while the two others may be regarded as maxillæ. Finally, the tubular sheath assimilates to the labium or lower lip, even in regard to its articulations. Sometimes the sheath is bifid, as in *Thrips;* sometimes it is divided into two plates, as in *Pulex*. The first of these genera is stated by Latreille to be the only one in which he has discovered palpi. He thinks that the parts taken for such by Savigny in *Nepa Neptunia* (see Plate CCXX. fig. 6, as described in the preceding note), are more probably the rudiments of an articulation of the sheath. Germar indeed admits four palpi as characteristic of a new hemipterous genus of the family of Cicadariæ, named *Cobax;* but Kirby, who about the same period published an account of another generic group under the title of *Otiocerus*, and which offers analogous parts, does not regard these as palpi, but as simple appendages accompanying the antennæ.[3]

In the dipterous order, such as gnats and common flies, the mouth exhibits a great resemblance to that of the preceding tribes.[4] The union of the different parts forms what is usually in that order called the trunk or *proboscis.* We can here also distinguish the component parts of sheath and sucker. The former in dipterous insects is divisible into three principal portions; 1*st*, the *support*, distinguished from the following by an angular elbow, and frequently by a small geniculated article; 2*dly*, the *stalk;* 3*dly*, the summit, formed by two lips, sometimes membranous, large, vesicular, dilatable, striated, exhibiting through the microscope a great number of tracheal ramifications; sometimes coriaceous, and either small and slightly distinct from the stalk, or slender, elongated, and forming a more obvious article, almost as long as the preceding division (as in genus *Myopa*). The support is remarkable in this, that it results from the prolongation of the cutaneous membrane of the anterior and superior portion of the head, or the epistoma, united with the parts representing the labrum, to the mandibles, the maxillæ, and the inferior portion of the labium, as far as the mentum inclusive. This character particularly distinguishes the present tribes from those of the hemipterous order. In other respects the sheath may be said to be constructed on the same plan. The centre of the superior face of the stalk also presents a groove or gutter for the reception of the sucker. The number of pieces in the sucker varies according to an arithmetical progression of three terms, of which the difference is always two,—2, 4, 6; but in all cases there are always two portions which are not paired, the one superior, representing the labrum; the other inferior, placed behind the pharynx, and the analogue of the tongue or hypopharynx. Among the Diptera, as well as in the suctorial tribe (*Pulex*), the latter portion is always scaly and piercing, and contributes, in common with the others, to the purposes of nutrition. It is otherwise with the Hemiptera, and this distinction forms a new character of separation between that order and the insects now under consideration. The parts representing the maxillæ always exist, and are frequently accompanied each by a palpus; but these maxillæ are soldered to the support, and are indistinct, except where their apical portion becomes moveable and elongated, and presents the form of a seta or horny lancet. This always takes place when the sucker consists of from four to six pieces. In the latter case two of them represent the mandibles; in the other, or where the sucker is composed of only four setæ, these are wanting, or merely rudimentary. Sometimes also the labrum, almost always vaulted and large, seems to offer the vestiges of another piece, which, under a fuller development, might no doubt be regarded as the epipharynx. Sometimes the support is very short, and in this case the pieces of the sucker leave the cavity of the mouth, and the maxillary palpi are inserted on the sides. The Hippoboscæ, or pupiparous Diptera, differ from all the rest in the absence of the sheath; for the palpi, under the form of two coriaceous elongated blades, perform its functions, and advancing in a parallel direction, cover and protect the sucker.

In accordance with the observations of Latreille, as well as with those of Savigny, Leclerc de Laval, and Professor Nitzsch, regarding the structure of the mouth in such of the hexapod insects as undergo no metamorphosis (*hexapodes homotenes*), the general plan of organization seems in these to be the same as among the polymorphous orders. In *Pediculus*, properly so called, the only known suctorial species of that division, the trunk (*rostellum*) consists of a small inarticulate tube, inclosing a sucker, and withdrawing itself at pleasure within a muzzle-shaped advancement of the anterior portion of the head. But the organization of these parasitical species requires a renewed and more careful examination. The genus *Ricinus*, although furnished with mandibles, maxillæ, and an inferior lip, has these parts greatly concentrated, after the manner of the Suctoria; and the labrum seems to perform the office of a cupping glass, a character unique and unexampled in this class of animals, and one which, in combination with certain other features, indicates a peculiar type.[5]

These are the principal modifications exhibited in the structure of the mouth by hexapod or true insects. In the opinion of Marcel de Serres, the parts named palpi (the antennulæ of some authors) enjoy, at least in the Orthoptera, a peculiar property, that of being the organ of the sense of smell. Lamarck again looks upon the palpi as exercising the faculty of taste. Latreille regards these opinions as ill-founded, so far as concerns a great number of insects, such as those in which the palpi are non-existent, undeveloped, or extremely minute: but he views them in a more favourable light in reference to certain other species. Thus, among the Coleoptera of the sub-family of *Xylotrogi*, the maxillary palpi of the males are laciniated or pectinated like some antennæ. In many other kinds the last article of the palpi is greatly dilated, and terminated by a pulpy substance.

---

[1] See Plate CCXX. Fig. 4 represents the mouth of *Cimex nigricornis;* *a* is the articulated labium, with the eyes at each side, and the first joint of each of the antennæ; this is the sheath for the other organs, and exhibits the groove on its oral surface; *b* is the sucker viewed from above, covered at the base for one third of its length by the tubulated labrum, and exhibiting at the extremity the straight united tip of the maxillæ, and the recurved ends of the mandibulæ; *c* is a view of the same parts separated, with the labrum removed to exhibit the expanded roots of the mandibulæ and maxillæ, the small opening of the pharynx, and the pointed lingua before it and between the maxillæ. Fig. 6 represents the mouth of another hemipterous insect, the *Nepa Neptunia* of Savigny, the labrum and palate being removed. The mandibulæ appear at the external sides, their summits with reflected spiculæ, and their roots near the pharynx flask-shaped. The tongue (in the interior of the figure) is trifid at the apex, underneath which the maxillæ arise, and exceed the mandibulæ in length. The labium, or central anterior portion, exhibits the groove for the reception of the other parts, and the oval raised marks towards the narrow end are the (supposed) vestiges of palpi.

[3] *Linn. Trans.* vol. xiii. p. 12.

[4] See Plate CCXX. fig. 7, where we represent the parts of the mouth of *Tabanus Italicus.* At *a* the mouth is shown as if opened, or the labrum and the mandibulæ and lingua separated, to expose the pharynx; *b* is one of the mandibulæ viewed laterally; *c* is one of the maxillæ with the articulated palpus, the last joint of which is greatly enlarged; and *d* exhibits the labium, with its fleshy lips.

[5] *Diction. Classique d'Hist. Nat.* t. ii. p. 436.

We have not hitherto attended to the singular order Strepsiptera of Kirby (Rhipiptera, Lat.), the characters of which were first given in the *Linnæan Transactions*. If we regard the insects of this order as possessed of genuine mandibles, we must of course include them among the masticating tribes; but as in many of the preceding orders, in which the parts of the mouth are feebly developed, the mandibles are observed to have become obliterated, there is reason to suspect that the parts regarded as such in Strepsiptera are rather maxillary, in which case the structure would approach that of the lepidopterous kinds.

We have entered into the preceding details in consequence of the great importance which is now attached to the study of the parts of manducation. Latreille indeed seems to be of opinion, that whenever it is possible to characterize genera by more obvious organs, the minuter parts should not be had recourse to; and he deems the principles of the Fabrician system liable to abuse, especially when Clairville's example is departed from of employing only the mandibles and palpi. But the truth is, that the use of the compound microscope is scarcely ever required in these examinations; and it cannot be denied that a knowledge of such essential parts is indispensable in the formation of natural generic groups. The general physiognomy is frequently deceptive, and we can rectify our views only by recurring to influential organs. Thus the *Sphex spirifex*, and some analogous species which differ from their congeners in the mode of providing for their young, and which therefore form a good natural group, are also distinguished by an alteration in the structure of the mouth, but could scarcely be separated from the primitive genus by characters drawn from any other parts.

Besides the parts of the mouth, the head of insects presents some other component portions which have received particular names. What Mr Kirby calls the nose is that upper and anterior portion to which the labrum is attached, and which corresponds to the *clypeus* of Fabricius. (See Plate CCXX. fig. 1, *a*, upper portion.) The latter term was originally applied metaphorically to the expanded or shield-like covering of the head of the Scarabæidæ, and the expression was not inapt; but when it came to be used as a general term in relation to the structure of all other kinds, it lost its propriety of application. Hence the term *nasus* or *nose* has been substituted, as well as that of *epistoma*, which signifies the *part above the mouth*. Between the nose and the labrum we find in many species the nostril piece or *rhinarium* of Kirby. It is very obvious in a New Holland beetle, *Anaplognathus viridiæneus*. The *postnasus* may be seen under the form of a triangular piece, below the antennæ and above the nose, and separated from the latter and from the front by a deeply impressed line. It is very distinct in that splendid Chinese beetle the *Sagra purpurea*. The *frons* or front of insects is the middle part of the face, bounded laterally by the eyes, anteriorly by the nose or after-nose and the cheeks, and posteriorly by the vertex. The *vertex* is the crown of the head, and is bounded laterally by the hinder part of the eyes and the temples, and posteriorly by the occiput, when that part exists. It is the ordinary region of the stemmatic eyes, although these peculiar organs are sometimes found to occur likewise upon the frons. The *occiput*, or hind head, is that part which either forms an angle posteriorly with the vertex, or slopes downwards from it. It is bounded laterally by the temples, and posteriorly by the orifice of the head, or by the neck itself. The cheeks, *genæ*, according to Kirby, usually surround the anterior part of the eyes, lying between them and the mandibles, or their representatives. The temples, *tempora*, form a continuation of the cheeks to the posterior limit of the head, forming its sides and posterior angles.[1]

The *subfacies* of an insect is the lower surface or under side of the head, and is composed, 1*st*, of the *lora*, a corneous angular machine, upon the intermediate angle of which the mentum sits, and on the lateral ones the cardines or hinges of the maxillæ: it is by means of this piece that the parts of the mouth (as in *Hymenoptera*) are pushed forward or retracted: 2*d*, of the *jugulum* or throat, which is that part of the subface which lies between the temples. The *collum*, or neck, is that narrow portion of a pedunculate head by which it is connected with the thorax.[2]

The next appendages of the head to which we have to direct the reader's attention are the *antennæ*. These are moveable articulated organs, never exceeding two in number in genuine insects, although their form, and the amount of articulated portions, are extremely various. Their primary use in the animal economy has not yet been ascertained: at least a great diversity of opinion is maintained on the subject. In numerous tribes they seem to exercise a faculty analogous to that of touch, being employed in exploring the depth of crevices, and in ascertaining by contact the nature of any opposing obstacle; while, on the other hand, their extreme shortness in most Diptera, and in many of the neuropterous and hemipterous tribes, does not accord with that usage. Although of considerable importance in our systematic arrangement of insects, the development of the antennæ does not seem subjected to any general or conformable rules, and is therefore of less value than that of several other parts of structure. For example, we frequently find a considerable difference to exist in the form of the antennæ among species in other respects intimately allied; and even between the sexes of the same species a great disparity in size and structure is observable. Where a difference exists, those of the male are generally more developed than those of the female.

The antennæ of insects are usually composed of small cylindrical articulations, containing nervous threads, muscles, tracheæ, and cellular tissue. Various terms are in use to express their form, consistence, and mode of insertion. They are *regular* when the articulations follow a gradual and progressive order in the modifications which they undergo: *irregular*, when their forms alter suddenly; *cylindrical*, when rounded and of equal diameter throughout their length: *filiform*, when the cylindrical shape is finely attenuated, like a thread or hair; *setaceous*, when lengthened, and diminishing insensibly from the base to the point: *subulated* or *awl-shaped*, when slender, but short, cylindrical at the base, and terminated by a stiff and sharpened point: *moniliform*, when each article is rounded like a bead, and of nearly equal thickness; *prismatic*, when approaching the form of a geometric prism: *ensiform*, when broad at the base, and terminated by an angular point: *fusiform*, when shaped like a spindle; *serrated*, when each article is terminated laterally by a sharp tooth directed forwards; *pectinated*, when these projections are straight, lengthened, and placed above each other, like the teeth of a comb; *ramose* or *branched*, when several appendages project from the main body of the antennæ—they are regarded as *simple* when not in any way so adorned: *perfoliated*, when the articles are flattened from the summit to the base, and appearing as if strung on a thread through the centre (it is usually the terminal portion of the antennæ that is so characterized); *imbricated*, when the articles are threaded as above mentioned, and concave at their summit, so that each covers the base of that which follows: *clavated* or *club-shaped*, when thick or swollen towards the summit. The club is *solid* when its parts are not separated by any apparent space; *perfoliated*, when composed of threaded articulations; *lamellated* or *foliated*, when the parts of the club are connected laterally, and admit of being opened and closed like the leaves of a book; *securiform* or *hatchet-shaped*, when the last articulation assumes the form of a compressed triangle, free at the base, but articulated by the apex. Antennæ are also said to be *uncinated* or *hooked* when the extremity suddenly bends itself towards the base; *bifid*, when divided into two: *obtuse*, when terminated by a round or blunted articulation; *truncated*, when apparently deprived of a portion; *plumose*, when thickly branched on either side, like a feather. Many other terms are in use to express the modifications of these important organs, most of which, however, are of a sufficiently familiar derivation to explain themselves.

---

[1] *Introduc. to Ent.* vol. iii. p. 483.

[2] *Ibid.* p. 366.

The antennæ of the coleopterous order usually consist of ten or eleven distinct articulations. The latter number is the most frequent, although several genera present much fewer joints, as for example *Paussus*, in which there are only two. Others again have many more, such as a species of Prionus, of which the antennæ of the female have nineteen joints, of the male twenty. In some orthopterous kinds these articulations amount to a hundred and fifty. The antennæ are inserted on the front of the head, anterior to and rather beneath the region of the eyes. Their particular position varies, but they are always either in the space between the eyes, or that below them. As their various forms, as characteristic of particular groups of species, will be afterwards described in the systematic part of the present treatise, we shall not here enter into further details of structure. The uses of these singular organs are variously viewed by naturalists, and there seems even yet to be more hypothetical reasoning on the subject than precise induction from facts. Some regard them as the seat of smell, others of hearing, a greater number as the organs of the sense of touch. The indurated nature of the outer covering in most insects would certainly lead us, *a priori*, to expect a special provision for the reception of the last-named sense. It is, however, extremely difficult, in the present state of our knowledge, to come to any general conclusion on the subject. We shall state the prevailing opinions when we come to treat of the senses of insects: and under that head we shall likewise explain the structure of the eyes.

The *thorax* forms the second principal portion of an insect's body. It is itself divisible into three parts, and its component segments vary greatly in their relative proportions in the different tribes; the division which is merely rudimentary in one particular group, being sometimes highly developed in another. These parts are named the *prothorax*, the *mesothorax*, and the *metathorax*.

The *prothorax* (from προ, *before*, and θωραξ, *thorax*) is the anterior segment, and corresponds to the *corselet* or collar of M. Latreille: the second segment is named *mesothorax* (from μεσος, *middle*); and the third is known as the *metathorax* (from μετα, *after*.) Each segment may likewise be distinguished in reference to its inferior, its lateral, and its superior portions; and the whole united constitute the *thorax*, commonly so called. But although the general name of thorax is applied to the parts just named, yet the posterior two, that is, the mesothorax and the metathorax, are the most dependent on each other, and are always intimately united: while the prothorax, as exemplified in the Coleoptera, is often comparatively free and distinguishable. It is this last-mentioned segment which bears the anterior pair of feet, and it considerably exceeds the others in extent. In the coleopterous order, indeed, it is the only part that is visible on the upper surface, the other segments, with the exception of the scutellum, being connected beneath it and the elytra. The mesothorax and metathorax unite strictly with the base of the abdomen, and serve as the points of attachment to the other pairs of feet. Of the mesothorax or central portion, the most obvious characters consist in its serving as a support to the second pair of feet, and to the elytra or first pair of wings. Its form, size, and consistence are extremely various. Slightly developed in the Coleoptera and Orthoptera, it is larger in the Hemiptera, the Neuroptera, and more especially in the Hymenoptera, the Lepidoptera, and the Diptera. Its excessive increase is always associated with a condition more or less rudimentary of the other segments. Thus, in the three orders last named, the prothorax and metathorax are very restricted; while, on the contrary, they are large in the Coleoptera, among which it is observable that the mesothorax is always compressed and narrow. The metathorax serves as the point of attachment to the third pair of feet, and to the second or membranous pair of wings.

We have said that each segment may be described in relation to its inferior, its lateral, and its superior parts. A piece named the *sternum* constitutes the whole of what is called the *inferior* portion. This is not, as too often supposed, an occasional projection, merely characteristic of certain tribes. It occurs in all insects, and forms a distinct character, though more or less defined and perspicuous, according to the genus. It may be regarded as generally composed of three distinct pieces, resembling in this respect the human sternum, which anatomists describe as consisting originally of three bones. Each of these pieces, according to Mr Kirby, is appropriated to a pair of legs, and each of them has been called the *sternum*; thus, in Elater the *prosternum*, in the Cetoniadæ the *mesosternum*, and in Hydrophilus the *metasternum*, have alike been distinguished by the name. Each of the ordinary *lateral* portions of the thorax is formed of two principal pieces, which, in combination with the sternum, is by some named the *pectus* or breast. The anterior piece rests upon the sternum, and is hence called *episternum* (from επι, *upon*). The posterior lateral portion, called the *epimera*, is connected with the preceding: it also adheres to the superior portion, and rests in certain cases on the sternum; but it bears a constant relation to the haunches of the segment to which it belongs, and to these it articulates by means of a little piece afterwards mentioned by the name of *trochantin*. It derives its name from επι, and μηρος, *thigh*. Lastly, there exists on these same lateral parts a third piece, in general slightly developed, and sometimes imperceptible. It bears relation to the wing and episternum, always supports itself on the latter, is sometimes prolonged inferiorly along its anterior margin, or, becoming free, passes in advance of the wing, or even places itself above it. It bears the name of *paraptera*, from παρα, *near to*, and πτερον, *wing*. Three other portions of some importance may likewise be considered as belonging to the general *pectus*.

External Anatomy.

1*st*, Above the sternum, on its internal face, that is, within the body of the insect, there exists a piece sometimes remarkable for its size. It is placed on the median line, and generally takes its rise from the posterior extremity of the sternum. It assumes various secondary forms, and is generally divided into two branches. Cuvier named it the Y-formed portion, on account of his having observed it assume the shape of that letter. It is called *entothorax* by M. Audouin, from εντος, *within*, because it is always placed in the interior of that organ. It occurs in each segment of the thorax, and seems to be in some measure a dependent on the sternum. Its uses are supposed to be the protection of the nervous system, and its isolation in many cases from the digestive apparatus and the dorsal vessel. The entothorax exists not only in the thorax, but in the head, in which case it is named *entocephalus ;* it has even been noticed in the first ring of the abdomen in the genus *Cicada*, and the portion named *triangle écailleux* by Réaumur may safely be regarded as its analogue. In this last condition it is denominated *entogaster*.

2*d*, On the anterior edge of the episternum, sometimes of the sternum, and even on the superior part of the body, a stigmatic opening is observable, surrounded by a small piece, of which the texture is frequently corneous. This is the *peritrema*, so called from περὶ, *round about*, and τρῆμα, *a hole*. It is not always perceptible, both on account of its being sometimes too closely connected with the neighbouring pieces, and because the stigmatic opening is itself sometimes obliterated. But when visible, it is necessary that it should be distinguished, as its position is of importance, and becomes a useful auxiliary in the comparison of parts and in the determination of analogies.

3*d*, Lastly, it has been already stated in relation to the epimera, that it is connected with the rotule by means of a small articulation, of which the existence was first made known by M. Audouin. This is not an essential part of the thorax ; but as it accompanies the epimera, and is associated with the parts of the leg, all of which have received particular denominations, its first describer has thought proper to bestow upon it a name. He calls it *trochantin*, in distinction to *trochanter*, or that portion of the leg which is associated with the rotule and the thigh. The trochantin is sometimes concealed in the interior of the thorax, and is sometimes visible externally, according as the rotule is itself more or less prolonged in its internal portion. The ascertainment of this piece, according to M. Audouin, admits of a direct comparison between the limbs of insects and those of the Crustacea. Hitherto there were only five parts in the former (the tarsi being regarded as one), while there were six in the latter. But the trochantin completes the number six likewise among the insect tribes.

We have now detailed the structure of the chest or pectus of insects ; so that whoever desires to view one of these creatures anatomically, should, after dividing the thorax into three segments, seek to ascertain, on the inferior and middle portion of each, the existence of a sternum, and on the flank or lateral portion, an episternum, a paraptera, and epimera. He will also study the structure of the entothorax, of the peritrema, and of the trochantin. Sometimes, however, the union of one or more of these parts with another is so intimate that they cannot be isolated or distinguished ; but when we elsewhere, in such numerous cases, perceive that the pectus is formed of a certain number of elementary parts, it is more rational to believe that in all instances these same elements are made use of, than to suppose the frequent requirement of new.

We shall next discuss the superior portion of the thorax of insects. In the coleopterous tribes the prothorax, as before mentioned, constitutes the principal portion, and its upper part may be called the *thoracic shield*. The only other part sufficiently distinguished prior to the time of M. Audouin, was the *scutellum* or escutcheon. It is highly developed in the Scutelleræ, and rudimentary in most of the Hymenoptera, Diptera, Lepidoptera, and some other orders. Its apparent position between the wings has occasioned its being regarded too exclusively as a kind of *point d'appui* in flight. It is usually of a triangular form in the Coleoptera, and projects backwards from the mesothorax, with its point interposed between the elytra and the wings. The scutellum was adopted by Geoffroy as the basis of his arrangement of the genus *Scarabæus*. It is, however, by no means a well-chosen characteristic of the greater divisions in entomology ; for the accurate distinction is not, as is usually supposed, whether the scutellum does or does not exist in a lamellicorn insect, but whether it is or is not apparent.[1] It occurs very obviously among many of the coleopterous tribes, but is most conspicuously developed in that genus of the hemipterous order called *Scutellera*, of which *Cimex lineatus* may serve as an example. Naturalists have erred in regarding this portion as characteristic of the mesothorax alone. It is often greatly developed in the posterior segment. Numerous and varied researches have led M. Audouin to conclude that this superior portion of the thorax is composed of four principal pieces, frequently isolated, sometimes intimately united, usually distinct. He has deduced the following nomenclature from their relative position in regard to each other. The anterior portion is named the *præscutum ;* it is sometimes very large, and is usually concealed in whole or in part in the interior of the thorax. The second piece is called the *scutum ;* it is an important element, often strongly developed, and always articulates with the wings when these exist. To the next piece the original term *scutellum* is applied ; it consists of the projecting angular point, generally so denominated by entomologists. The fourth and last piece is called the *postscutellum ;* it is almost always entirely concealed within the thorax, sometimes united to the internal face of the scutellum, and confounded with it, sometimes free, and not adhering to the other portions, except by its lateral extremities. These are the parts which constitute the superior portion of the thorax, and to which the general term *tergum* may be applied. Thus we may speak of the tergum of the prothorax, of the mesothorax, or of the metathorax ; but when the word tergum alone is used, we are then understood to signify the union of the superior parts, that is, the entire space comprised between the head and the first segment of the abdomen.

We come now to the *abdomen* itself, an important portion in the animal economy. Anatomists in general appear to have advanced from the study of the human frame to that of animals, or at least to have applied to the parts of the latter the same terms which they had previously bestowed upon the former. In so doing, however, they have been guided rather by the analogy of form than of function, and hence the vague nature of many terms, as applied to the inferior orders, and which, however correct in their original signification, become either obscure, or altogether inapplicable in regard to other classes.

The abdomen, among insects, is that part of the body which is attached to the posterior extremity of the thorax, composed of five or six rings or segments, unprovided with locomotive organs, and always containing within it a portion of the digestive canal. If, as many suppose, its existence depends upon that of the thorax, then the entire class of Annelides or red-blooded worms may be said to be deprived of it, as the thorax itself does not exist in that class.

---

[1] *Horæ Entomologicæ*, part i. p. 9.

The term body is then made use of to designate generally the whole of the animal. Although the abdomen cannot well exist without the thorax, the converse does not appear to hold good, for the latter in many species seems to constitute the whole body. Many of the *Myriapoda*, such as Iulus and Scolopendra, are examples of this; for they are composed of a series of segments, all furnished with feet except the last, which has therefore by some been regarded as the abdomen.

But among genuine insects, that is, the hexapod or six-footed kinds, the abdomen is obviously developed, and, especially among the winged tribes, is very distinguishable from the thorax. Among the apterous species the distinction is less perceptible; and the same may be said of most insects in the larva state. Among the hymenopterous kinds, such as wasps, bees, &c. it appears as if it were pediculated or attached to the posterior part of the thorax by means of a slender stalk; but minuter and more accurate observation demonstrates that this neck-like restriction actually takes place on the second segment of the abdomen, the first of which is much more spacious, but so closely attached to the thorax by its anterior edges as to become undistinguishable. In the coleopterous order the abdomen is usually convex, and of a harder consistence beneath, where it is exposed; but it is soft, and either flattish or concave above, where it is covered by the folded wings and elytra. On both sides of its segments there is a small roundish opening called the *stigma*, which serves for the introduction of air for the purposes of respiration, and of which we shall treat in detail when we come to the consideration of that function.

It has been noted that if an insect is naturally more habituated to walking than flying, the breast or lower portion of the thorax is expanded, and is furnished with more powerful muscles than the back; whereas, if flight is the more frequent mode of locomotion, an increase is observable in the dorsal muscles. The locomotive organs are of course the wings and legs, on which we shall now bestow a brief consideration.

SECT. III.—ORGANS OF LOCOMOTION IN INSECTS.

1. *The Wings.*

These organs exist, effectively, in insects only in the perfect state; for the larvæ do not offer externally any trace of them, and when apparent in the nymph or intermediate condition, they are merely rudimentary. No insect has more than four wings, many have only a single pair, and others are entirely destitute of these parts. When four in number they may be regarded as *anterior* or *superior*, and as *posterior* or *inferior*; and we likewise talk of the *first* or of the *second pair* of wings. The coleopterous order presents some peculiarities in relation to these organs. The anterior pair (in all cases, as already mentioned, united to the mesothorax) consist of a hard or horny substance similar to the envelope of the thorax, and are called *elytra*. When closed, their junction usually forms a straight central line called the *suture*, which is rather apparent than real in certain species in which the inferior wings are wanting, and the elytra form a single undivided piece. They are convex above and concave below, are fixed to the mesothorax, and cover and protect the genuine wings, which are of a much more delicate structure. These latter derive their origin from the metathorax, and are the actual organs of flight. They are membranous and transparent, and when unemployed are transversely folded beneath their horny covering. We shall here describe the structure of wings, and explain the terms made use of to express the principal modifications which they undergo in their various degrees of development in the different orders.

The wing of an insect consists of two thin flexible membranous transparent plates or leaves, the one superimposed upon the other, and variously intersected by darker lines of a horny consistence, usually known by the name of nervures. These nervures, which at first sight appear like superficial threads, of which the larger follow the longitudinal direction of the wing, are interposed between its membranes, and present two faces, of which the upper, frequently rounded and very horny, adheres closely to the corresponding leaf, and the under, of less firm consistence, and of a flatter form, may by skilful dissection be removed from that portion of the wing by which it is covered. In the opinion of M. Audouin, these threads are in fact so many tubes, which diminish in diameter as they approach the summit of the wing, and each of which contains, throughout its entire extent, a spirally rolled vessel, by some regarded as a genuine trachea. These tracheæ receive air from the interior of the body, and their formation, according to Swammerdam, whose views have more recently been confirmed and adopted by Jurine and Chabrier, is to strengthen the wing by distending it during the action of flight. They are said to experience no sensible dilatation during their progress, whereas the corneous tubes which contain them present in that respect some curious modifications,—for they sometimes spread out suddenly, in such a way as to exhibit, for a short space, a comparatively broad diameter. The colouring matter being then disseminated over a wider surface, assumes so pale an aspect that the nervure which leads into one of those little expansions appears as it were interrupted. Hence the name of *bulles d'air*, or air-bubbles, bestowed upon the latter by the French entomologists. They occur most frequently in the cubital nervures of many Hymenoptera, and their chief use is supposed to be to facilitate the formation of certain foldings of the wing during the periods of repose. The largest of the nervures arise from the base of the wing, that is, from the point of its insertion in the thorax. A most skilful observer, the late M. Jurine of Geneva, has described the wings of hymenopterous insects with great accuracy, in a memoir to which we shall make more special allusion when we come to treat of that particular order.[1]

The general character in respect to form and aspect of the wings of insects has received a great variety of names. They are sometimes *equal*, that is, all four of similar size; or *unequal*, when one pair prevails over the other; *lanceolate*, when they become narrow, both at the base and apex; *falcated*, when curved like a scythe or reaping-hook; *linear*, when narrow, with nearly parallel edges; *clavated* or *club-shaped*, when linear in their general extent, but perceptibly enlarged towards their extremity; *rounded*, when they approach a more circular form; *oblong*, when more lengthenened than broad, and describing an elongated ellipse, obtuse at both ends; *rhomboidal*, when they are longer from the posterior angle to the summit than from that angle to the base; *deltoid*, when they assume the triangular form of the Greek letter delta; *exserted*, when the inferior wings pass beyond the elytra; *covered*, when entirely protected by those organs; *plaited*, when longitudinally

---

[1] See *Observations sur les Ailes des Hyménoptères*, in the twenty-fourth volume of the *Mem. de l'Académie des Sciences de Turin.* Consult also, by the same author, *Nouvelle Méthode de classer les Hyménoptères et les Diptères.* Genève, 1807.

External Anatomy.

folded, after the manner of a fan; *replicated,* when, after being plaited as just mentioned, they are again folded transversely upon themselves; *incumbent,* when the posterior margin of one covers that of the other; *extended,* when, in a state of repose, they are stretched on either side, leaving the abdomen visible; *erect,* when, in a state of repose, they are raised perpendicularly to the surface of the body; *deflexed,* when the summits and outer margins form as it were a kind of inclined plane from the base and inner margins. These are the principal variations as to form and attitude, or position. The following terms are of frequent use in entomology, when the surface or superficial structure of the wings is sought to be described. They are *striated,* when certain raised lines are perceptible, forming slight parallel and longitudinal furrows; *reticulated,* when these lines are disposed like lace or network; *veined,* when distinct longitudinal nervures are observable, ramifying into more delicate branches; *squamous* or *scaly,* when covered with minute powdery particles, which, when examined with a glass, are found to be small scales imbricated or imposed on each other like slates or tiles on a house top; *farinose,* when sprinkled more irregularly with fine particles resembling flour, and easily removeable by the finger; *pilose* or *hairy,* when the surface is more or less covered by minute hairs; *naked,* when there is no covering of either hairs or scales. Other characters are deduced from the markings of the wings in regard to tint and colour. They are *concolorous,* when similar or unvaried in their hue; *vitreous* or *windowed,* when, opake over their general surface, certain translucent spots are here and there observable; *ocellated,* when they present circular spots of different colours, resembling an eye; *pupillated,* when the eye-like spot has a coloured point in its centre; *fasciated,* when there are broad coloured lines or bands,—and these are distinguished as transverse, longitudinal, oblique, lanceolated, &c. according to their prevailing direction and characteristic form.

The margins or edges of the wings have likewise received a considerable variety of designations, according to the peculiar characters which they exhibit. They are *crenated,* when they present an alternation of slight incisions and obtuse projections; *dentated* or *toothed,* when these incisions are deeper and narrower, and the projections sharper and more defined; *fimbriated,* when the marginal processes are lengthened, pointed, and close; *cloven,* when the incisions are few and deep; *digitated,* when the parts cut into assume the aspect of a hand; *emarginate,* when the incision is slight, and seems merely to have scooped out a small portion of the wing; *caudated* or *tailed,* when the posterior margin presents a more lengthened appendage; *ciliated,* when the wings are bordered by close-set hairs resembling eye-lashes. The points of the wings are *obtuse,* when terminated by a rounded outline; *truncated,* when they appear as if cut; *acute,* when ending in a point; *acuminated,* when that point is sharp and prolonged.

These details, we doubt not, like all the other technicalities of a complex branch of science, must seem irksome to the general reader. Nevertheless, as they frequently form important and sometimes indispensable elements of knowledge, we must continue their enumeration. The wings, in fact, have furnished the characters from which the names and definitions of the orders in entomology have been derived, and a knowledge of their forms and functions is required during almost every step of our progress. A transcendental anatomy has no doubt thrown its ambiguous light (*lucus a non lucendo*) upon these and other portions of animal economy; and the wings, which in former times were thought sufficiently defined when merely named as the organs of flight, are now regarded by some as legs, and by others as lungs. We still see, however, that they carry the creatures through the air, and we shall therefore rest satisfied by viewing them in accordance with our accustomed associations.

Among the more remarkable of the modifications experienced by the upper wings, is that corneous condition in which they are known under the name of *elytra.* These are particularly characteristic of the coleopterous order, and derive their name from ἔλυτρον, a sheath or covering, because they protect the membranaceous wings. They are attached by their base, by means of several small pieces, to the mesothorax. The opposite extremities are called the points or summits, and the margins are known as anterior or external, posterior, and interior,—the last named, when the parts are closed, and meeting over the back, forming what is called the dorsal suture. As to their proportions, they are *elongated,* when they exceed the abdomen; *abbreviated,* when shorter than that organ; and various other terms of obvious application are made use of to express their different degrees.

The elytra differ in their consistence, being sometimes almost *membranous,* or scarcely firmer than the under wings; or they are *coriaceous,* or of the texture of leather; *semi-coriaceous,* when, as among many Hemiptera, the elytra are composed of two parts of different texture; *pergameneous,* or like parchment; *flexible,* when, yielding to a slight impression, they yet return again immediately to their original shape; or *soft,* when they yield to the same impression, but retain the alteration of form for a longer time. As to form, many of the terms already enumerated in relation to the wings in general, apply equally to the elytra. They are also *gibbous,* when greatly rounded or hemispherical; *dilated,* when more flatly expanded; *attenuated,* when they diminish in breadth from the base to the apex. The surface of these parts presents many characters of great importance in the discrimination of species, and even in the formation of sections or subdivisions of genera. They are said to be *chagrined,* when covered by minute *raised* spots; *punctated,* when these spots are distinct and *hollowed; tuberculated,* when the elevations are distinct and irregular; *scabrous,* when the elevations are distant and unequal; *verrucose* or *warty,* when they are large, cicatrised, and resembling warts; *striated,* when marked with regular longitudinal lines; *striato-punctate,* when in each stria there are depressed points; *punctato-striate,* when the striæ are themselves formed by a consecutive series of these impressed points; *sulcated* or furrowed, when the impressed lines are deep and broad; *ribbed,* when between the furrows there are raised lines; *rugose,* when the raised lines are irregular, and divided in all directions; *reticulated,* when these lines are disposed with greater regularity, in a kind of network; *crenated,* when the lines are rather regularly undulated; *glabrous,* when the elytra are smooth, or destitute of raised points or other irregularities of surface; *tomentose* or *cottony,* when covered by a whitish down; *pilose,* when hairy,—also *villous; fasciculated,* when the hairs are collected here and there in little tufts; *muricated,* when the hairs are long, raised, and almost prickly; *spinous,* when the projecting parts are hard and sharp like spines; *squamous* or *scaly,* when covered by little scaly plates.

The elytra are said to be *margined* when their edges are raised, or otherwise distinguished from the general and more central surface; *sinuated,* when there are sloping notches on their outline; *serrated,* when furnished with little sharp projections like the teeth of a saw; *dentated,* when these are sharp and more distant. They are likewise said to be *mucronated* when the apex is provided with a sharpish point; *bidentated,* when there are a couple of distinct projections; *obtuse,* when the summits are blunt or rounded; *truncated*, when they seem as if a portion had been severed.

We have already mentioned, that in many of the hemipterous order the anterior wings are *semi-elytrous*, that is, comparatively solid in one part of their extent, and membranous in the other. In fact, the order derives its name from that character, as already mentioned in our introductory definitions. In the orthopterous order the anterior wings, though much more membranaceous than those of beetles, yet approach the nature of elytra, and serve as a protection to the under pair, which are more delicate. Among neuropterous insects both pairs of wings are alike in their general character of texture and reticulation, and the same may be said of the hymenopterous order. Those of the Lepidoptera are also similar to each other in their substance and covering. With a few exceptions, in which the wings are clear or diaphanous, in the last-named gorgeous group they are thickly coated with minute scales of various colours, which when removed exhibit the membranous structure of the parts. They present several other peculiarities, which we shall notice when we treat of the generalities of the greater divisions of which the order is composed.

The wings, regarded throughout the entire series of hexapod insects, are thus extremely varied in their form, consistence, development, and efficiency. The distinctions, both of form and texture, show themselves, as it were, by gradation, and present no striking disparity among species otherwise nearly allied. But the uses, and degrees of development, of these organs, vary greatly not only among species of the same genus, but even between the sexes of the same species; for while the males of several kinds are efficiently winged, the females are entirely apterous. When the anterior wings, as in the Coleoptera, are *elytrous* (if we may use the expression), they scarcely serve for the purposes of flight. In the neuropterous and hymenopterous orders both pairs are equally efficient, while in the dipterous or two-winged tribes the inferior wings have disappeared. In some cases, as among the female ants, the wings fall off immediately after the sexual union.

The development of the wings always bears a relation to that of the superior arc of the thorax by which they are supported. It has been already noted, that if an insect is more habituated to walking than flying, the breast or lower portion of the thorax is extended, and is furnished with more powerful muscles than the back; whereas if flight is the means of locomotion, an increase of power is observable in the dorsal muscles.

One of the laws laid down by M. Straus Durckheim as regulating organic structure is the following:—that when one organ governs another, or several others, these follow the march of the dominating organ; and that when the latter disappears, those which were subordinate to it immediately assume their primitive form. This law may be exemplified by the influence of the wings upon the thorax. In proportion as the two pairs of wings change in form and size, the two segments of the thorax which support them follow the same progression, and become more and more united to each other; but no sooner do the wings disappear in the Aphaniptera (Pulex), than the two segments of the thorax regain their primitive form, and separating from one another, present the same appearance as in Lepisma. The wings being first introduced amongst the Coleoptera, and the thorax of these as yet differing but little from that of the Thysanura, it can easily return to the form it possessed previously to its undergoing any modification. It thence follows, that in such species as are deprived of wings, the thorax returns more or less to its primitive form. This is particularly remarkable in the females of many species of *Lampyris*, which possess neither wings nor elytra; and this return is moreover occasioned in the Coleoptera without wings by another cause, which acts in this case on that part of the body; it is the diminution of the solidity of the integuments in those parts which are covered by the elytra.

In the other order of insects, according to the views of the last-named author, the two segments which bear the wings having already experienced a very considerable change of form, it would require a very powerful cause to bring them back to their primitive form; for this reason the return does not take place in *Cimex cellularius*, the *Formicæ*, &c. amongst which the imperfection (if it may be so called) is only specific. In the Aphaniptera, on the contrary, which we may in some respects consider as wingless Diptera, the transformation of the thorax takes place in consequence of a complete absence of the wings, brought about by the degradation which these organs have experienced in passing through the whole of the class Insecta.

M. Straus Durckheim, in the introduction to his carefully elaborated work,[1] has also endeavoured to explain the laws which regulate the different changes of structure in passing from one group to another. The most general law in the organization of animals which he has recognised is, that all the systems of organs are subjected to a constant variation of form, and even of function, while passing from one family to another. The first more special or particular law which he evolves from the subdivision of the former is the following: That the organs at one extremity of the scale always exercise a very evident function; whilst at the other extremity they are constantly rudimentary and without function, and at last entirely disappear. He here distinguishes two kinds of cases. In the first, the organs present themselves at the head of the scale developed to the highest degree of which they are susceptible, and decrease insensibly, until they arrive at the other extremity of the scale. Thus, for example, the posterior wings of insects are "introduced suddenly" into the organization of that class at the highest point of perfection in the Coleoptera, where *they* alone serve for flight. In the Orthoptera and Hemiptera they already begin to divide their function with the elytra, and go on diminishing gradually until they exist merely as rudiments in the Diptera, where they are represented by the halteres.[2] Finally, they entirely disappear in the Aphaniptera. In the second instances, the organs do not appear at the head of the scale in their most perfect state of development, and only acquire it by degrees. Such is the case with the elytra, or first pair of wings, which follow a course exactly contrary to that of the inferior wings. They only appear at first as organs slightly accessory to flight, in which state they remain nearly throughout the whole Coleoptera. In the Orthoptera and Hemiptera they begin already to take a very active part in

[1] *Considérations Générales sur l'Anatomie Comparée des Animaux articulés, auxquelles on a joint l'Anatomie descriptive du Hanneton*, 1 vol. 4to, avec planches, Paris, 1828. An abstract of the doctrines of this work will be found in the *Entomological Magazine*, vol. i.

[2] The name of *Halteres*, poisers or balancers, is bestowed on a pair of slender moveable appendages found on the hinder part of the thorax in dipterous or two-winged insects. They are usually regarded as the rudiments of the second or posterior pair of wings,—"halteres rudimenta alarum posticarum," as Fabricius has expressed it in his *Entomologia Philosophica*. This opinion, however, is believed by others, and we think with reason, to be founded rather on the position which these organs bear in relation to the anterior wings, than on their connection with the metathorax and its different parts. Latreille, a great authority in such matters, maintains that the balancers do not correspond to or represent the second pair of wings, but are rather vesicular appendages connected with two posterior tracheæ of the thorax, and analogous in some measure to the processes which accompany the respiratory organs of the Aphro-

External Anatomy.

Internal Structure.

flight, but still preserve their primitive use. In the Neuroptera, particularly the Libellulina, they attain the development of the inferior wings, from which they differ but very slightly. From this point they continue to surpass them, until in the Diptera they become the sole organs of flight, and of course have there attained their highest degree of perfection. Arrived at this culminating point, they suddenly diminish in Hippobosca, and entirely disappear in Pulex.

We shall next devote a few lines to those portions of the wings called *ailerons* by the French naturalists, known also under the name of winglets or *alulæ*.[1] They are chiefly characteristic of the dipterous tribes, and may be regarded as appendages of the anterior wings, the sole pair in that particular order. Their attachment to the scutellum and the postscutellum of the mesothorax is sufficient evidence that they are not the rudiments of a posterior pair; for these, if they existed, would derive their origin from the metathorax. They usually consist of two concavo-convex pieces, intermediate as it were between the wing and the poisers, and folded the one upon the other, like the parts of a bivalve shell when the insect is at rest, but stretched or extended during flight. Their special uses are not yet known.

The poisers or balancers (*halteres*) have been sufficiently described in the preceding note. Audouin regards them as the rudiments of the second pair of wings, of which the extreme tenuity in the Diptera accords in his opinion with the evanescence of the metathorax.[2] Their use, like that of the last-named organs, seems not to have been satisfactorily determined. Dr Derham and others have thought that, like the pole of a rope-dancer, they keep the body steady in flight; while some connect them with the noises produced by insects, and maintain that they act upon the membrane of the winglet, as a drumstick acts upon its proper organ, thus producing sound. Shelver's opinion is probably more correct, that they are connected with the function of respiration.[3] But the various sentiments on the subject are as yet conjectural.

2. *The Legs.*

Having now endeavoured to explain the structure of the wings or organs of flight, we shall next request the reader's attention to those other organs of motion, the legs of insects. With the exception of the Myriapoda (*Centipedes*, &c.), which, with Latreille and Dr Leach, we shall form, as already noted, a separate class, the number of legs in insects is precisely six. They are composed of the following parts: 1*st*, The *coxa* or haunch, which is the first joint, or that which plays in the socket (see Plate CCXX. fig. 2, *a*); 2*d*, the *trochanter* or second joint, to the side of which the thigh is attached, and by means of which it inosculates with the coxa (Ibid. *b*); 3*d*, the *femur* or thigh, which is long, and usually compressed (*c*); 4*th*, the *tibia* or shank, generally the longest joint of the leg, and frequently notched on its edges, and terminated by spur-like appendages (*d*); 5*th*, the *tarsus*, composed of articulate portions, varying from three to five among the Coleoptera and the majority of insects (*e*). The last articulation of the tarsus bears the *ungues* or claws (*f*). M. Audouin and some other French naturalists seem to use the term haunch (*hanche*) as a collective designation, including an internal portion formerly noticed, called *trochantin*, along with the *rotule* (our coxa), and the trochanter. In accordance with this view, the parts of the leg in insects may be said to amount to six pieces, instead of the five which we have just enumerated. These terms apply strictly to the intermediate and hind legs. The anterior pair are by some writers regarded as *brachia* or arms. The first joint of the brachium, answering to the coxa of the legs, is named *clavicula*, or the clavicle, by Mr Kirby; its second joint, answering to the trochanter of the other limbs, is called the *scapula*; the third and elongated joint, corresponding to the femur, is designated the *humerus*; while the articulations of the tarsus are known as the *manus* or hand. However, the majority of authors seem not to express any distinction between the parts of the fore legs and those of the intermediate and hind ones. The anterior pair, we may observe, are in some cases convertible into organs of prehension, and their tarsi are frequently dilated in the male sex. The number of articulations of the tarsi varies in the different tribes, and is not always the same in the different pairs of legs in the same insect. Their amount on each limb has been assumed as a basis for the formation of the great sectional divisions of the coleopterous order, as originally proposed by M. Geoffroy, and so generally adopted by the continental naturalists. The character, though arbitrarily chosen, and not seldom artificial in its results, has proved upon the whole more compatible with a natural arrangement than usually happens on the selection of a single and uninfluential organ. We shall enter into further details in relation to this matter in our introduction to the coleopterous order, and shall merely observe in the mean time, that pentamerous species, or those of which all the tarsi are furnished with *five* articulations, are the most abundant,—more than one half of the coleopterous kinds being referable to that section.

These are the principal external parts of the structure of insects.[4] Their internal conformation has been illustrated of late years by the successful efforts of several very skilful and ingenious observers. We shall here notice the dominating or more influential organs, and give a short view of the important vital functions which they exercise.

CHAPTER III.

THE INTERNAL STRUCTURE AND PHYSIOLOGY OF INSECTS.

SECT. I.—THE NERVOUS SYSTEM AND SENSES OF INSECTS.

The nervous system of animals in general, it has been remarked, is one of the most wonderful and mysterious works of the Creator. Its pulpy substance is the visible medium by which the governing principle (Το ʽΗγεμονικον) transmits its commands to the various organs of the body, which instantaneously obey the impulsive mandate; yet this appears to be but the conductor of some higher principle, or

---

dites, or those of the aquatic larvæ of Ephemeræ and the genus Gyrinus. He founds his opinion chiefly on this, that the inferior wings always take their origin from the lateral and anterior summits of the third thoracic segment, at a very short distance from the superior wings, and always in advance of the two posterior stigmata of the thorax, whilst the balancers are inserted lower down at the internal extremity of these air-conduits, or close by them. (See Latreille's observations in the 7th and 8th volume of the *Memoires du Museum d'Histoire Naturelle.*)

[1] We have made use of the term *wing-scale* in the systematic exposition afterwards given of the order Diptera. Meigen uses the German word *schuppchen* (squama) in his *Zweiflugeligen Insecten.*

[2] *Dict. Class. d'Hist. Nat.* t. ii. p. 141.

[3] Wiedeman's *Archiv.* ii. 210.

[4] For some additional details, we beg to refer to a paper entitled "Osteology, or External Anatomy of Insects," by Mr Newman, in the *Entomological Magazine*, No. IV. We had not an opportunity of consulting it until our own abstract had been composed, chiefly from foreign sources.

more ethereal essence (language is ransacked in vain for an appropriate term), which can be more immediately acted upon by the mind and will. But this supposed principle, by whatever fond or fantastical name it may be known, whether as a nervous *fluid* or a nervous *power*, has never been detected by the most subtile physiologist, and is known only by its effects. It is, however, undoubtedly the centre from which all power and function flow; and during the absence of worthier substitutes we need not challenge the vague abstractions of some metaphysical inquirers.

The nervous system of insects consists of a homogeneous pulp, usually disposed in twelve successive ganglions, connected by a double cord. We first observe a double or bilobed mass, which, as it is placed in the head, may be called the brain. It is surrounded by strong muscles, and from its anterior portion nerves are distributed to the eyes, antennæ, and mouth. Posteriorly two delicate recurrent nerves proceed towards the dorsal vessel, and inferiorly two larger nerves, after having formed by their branching a kind of ring, which embraces the œsophagus, unite in the form of a ganglion beneath the last-named organ. From the posterior part of this latter ganglion a pair of nervous cords proceed for a space, and then by their union produce a second inferior ganglion, from which the nervous cords again branch off posteriorly, and so uniting and ramifying from space to space, they extend through the different segments of the thorax and abdomen. The number of these ganglia varies; sometimes they correspond to the divisions of the body, while in many instances they are of smaller amount. In the larva of the rhinoceros-beetle, for example, the whole spinal cord (so called from its supposed analogy to the part known by that name among the vertebrate kinds) presents the appearance of a single ganglion, divided merely by transverse furrows,—while in that of a dragon-fly, six have been observed in the thorax, and seven in the abdomen. In the great water-beetle (*Hydrous piceus*) the head exhibits one ganglion, the thorax six, and the abdomen only two. In the honey-bee there are three ganglia in the thorax, and four in the abdomen. When we examine these knots attentively, we may perceive that, in addition to the double and longitudinal nervous cord by which they are connected, they throw off laterally on either side small nervous trunks, which divide into branches, and finally ramify over the muscles, the intestinal canal, the tracheæ, and other parts. This nervous system differs considerably in the larva and perfect insect. In the latter the ganglia are usually less numerous, and the posterior appear formed by the close approximation of several others.

The principal ganglia of the nervous system of insects are frequently thus disposed. The position of the upper or cervical ganglion has been already mentioned. The others rest beneath the intestines, ranging along the inferior face of the body. There are three in what may be called the chest; that is, one in the prothorax, which sends nerves to the anterior legs; one in the mesothorax, which supplies the elytra or the upper wings, and the middle legs; and one in the metathorax, which distributes its filaments to the second pair of wings and the last pair of legs. The other ganglia belong to the abdomen. Insects are characterized by the ganglionic distribution of the nervous system, in common with the Crustacea and Arachnides on the one hand, and with the Vermes or worms on the other. But in insects the ganglia are larger and less numerous than in the still lower tribes, which gives a more decided character of centricity to their nervous system. Indeed the highest manifestation of this character is usually presented only as the ultimate result of several metamorphoses; so that while the larva exhibits a closer agreement with the nervous system of worms, that of the imago or perfect insect assumes a higher development. It does not however appear that the brain or upper ganglion of insects acts in the capacity of a *sensorium commune*, as among warm-blooded animals, such as mammiferous quadrupeds and birds; for many insects will live for a considerable time, and even exercise their faculties of flight, after the loss of parts which among the other class we justly regard as of vital importance. The tenacity of life in horse-flies, for example (*Hippoboscæ*), is very remarkable. When deprived of their heads, and replaced upon a horse, they will be perceived to run backwards and forwards and sideways, with apparently the same ease as prior to their decapitation.[1]

The ganglions themselves frequently exhibit a bilobed structure, which appears to result from the union of two smaller masses, originally distinct. Comparative anatomy tends to confirm this supposition. M. Marcel de Serres[2] maintains that the nervous system of insects, and of all invertebrate animals, corresponds to the eccentric portion of that system among the higher classes, that is, to the intervertebral ganglia and their radiations.[3] In the primitive state of larva he deems the nervous system to consist of two distinct portions, a right and a left; and he maintains that the formation of the nervous system in all animals proceeds from the circumference to the centre, and not, as usually supposed, from the centre to the circumference. We know well, from the observations of Carus and Tiedeman, that the organs of the inferior animals repeat, as it were, the forms which present themselves only in the *embryo* condition of the higher tribes. M. de Serres endeavours to show that it is by the progress of successive developments that the portions of the nervous cord in insects approach each other,—that they first join around the œsophagus, then at the opposite extremity towards the inferior ganglions, and lastly in the central parts. He thus admits three distinct embryo states in the condition of the larvæ; first, that in which the two portions of the nervous system are entirely isolated and distinct; secondly, that in which the œsophagian ganglia are alone united; and, thirdly, that in which the opposite extremities are joined together. By means of this distinctive view, the French physiologist connects the nervous system of insects with that of the Mollusca, the latter presenting the embryo con-

---

[1] *Entomological Magazine*, No. iii. 301.

[2] *Ann. des Sciences Nat.* t. iii. p. 377.

[3] The relation which the nervous system of invertebrate animals bears to that of the vertebrated tribes has, however, given rise to many conflicting opinions. "Among the various suggestions on this point, are that of Ackermann and Reil, who viewed the nervous system of Articulata as corresponding to the sympathetic system of vertebral animals;—of Walther, who compared it in the Mollusca to the par vagum, and in the Articulata to the spinal marrow;—the most generally received opinion, however, is that supported by the authority of Meckel, Cuvier, Blumenbach, Gall, and Spurzheim, who compare it in the Articulata to the cerebro-spinal cord of vertebral animals. The latter gentlemen, in particular, have furnished a strong proof of the correctness of this idea, by demonstrating that the spinal cord of the superior animals actually consists of a series of ganglia with intermediate contractions,—a structure most fully developed in the Articulata. Rudolphi (*Physiologie*, b. ii. s. 8, 1823) adopts the same opinion, and notices the fact, that in Mollusca, Crustacea, Insects, &c. we find nerves of sense arising from the cerebral ganglia,—which by no means accords with the character of the sympathetic system." (See Note to Carus's *Comparative Anatomy*, by Gore, vol. i. p. 69.) E. W. Weber (*Anatomia Comparata Nervi Sympathetici*) appears to have been the first to suggest that the ganglia on the knotted spinal cord of articulated animals correspond to the intervertebral ganglia of the spinal nerves of the higher classes, rather than to the segments of which their spinal marrow is composed.

Internal Structure.

dition of the former, that is, being permanently distinguished by a characteristic which is only temporary among the articulated tribes. This may probably be regarded as an additional argument in favour of what we shall afterwards endeavour to maintain,—the general superiority in the scale of organization of the annulose classes over the molluscous kinds. We shall conclude by observing, that besides the general protection afforded by the external envelope of insects to their nervous system, it is specially protected by the Y-shaped portion formerly described.

As the nerves constitute the principal media of sensation in all animals, we shall here give a short sketch of the different senses of the insect class.

Of the senses in general, as they exist in man and the higher beings, physiologists and metaphysicians alike enumerate the following *five*, viz. *touch*, *taste*, *smell*, *hearing*, and *sight*. All of these, we doubt not, exist in the class now under consideration, although we are not in every case acquainted with the special organ by which each particular function is exercised.

The sense of *touch* is usually regarded as affording animals, and man especially, a more intimate and assured communication with the external world than those of either sight or hearing, in as far as no intermediate substance comes between us and the subjects of perception. The perfection of the sense depends on the quality of the skin, the extent and nature of its surface, the number of its nerves, its freedom from insensible parts, and the delicacy of those appendages which are more particularly destined to the examination of bodies. As touch is the most important of all the senses, it may naturally be inferred to be finely developed in the human race; and we know that, of all the vertebrated animals, man in that respect is one of the most highly organized. But among the invertebrate kinds the sense of touch improves in proportion as the others degenerate; and those which have no other sense possess it so exquisitely that some of them seem even to *feel the light*.[1]

Among insects the sense of touch varies remarkably according to the condition in which they happen to exist for the time,—their exterior surface, in which the function exists, or at least through which it must be manifested, being itself subject to great variation, even among individuals of the same species. When soft, as in the larva state, the skin is extremely delicate in its perceptions, and capable of transmitting the most lively sensations; while in the imago or perfect condition, more especially among the Coleoptera, its harder consistence renders it chiefly serviceable as a protecting covering. In this case the feet, palpi, and, as many suppose, the antennæ, seem the principal organs of the sense of touch.

The sense of *taste*, which some regard as an exalted modification of the perception of touch, is very obvious among insects. We see many species, while searching after food, reject or only partially consume whatever is disagreeable or unexpected, while they gloat over a more favourite morsel. The organ in which the sense is placed is not, however, so easily determined. Some regard the palpi, and others the pharynx, as its principal seat. That portion of the labium which the French naturalists name the languette or ligula, has also been regarded as exercising the sense of taste. It is certain that distinct nerves are distributed to that quarter, as represented by Lyonnet in his great work on the caterpillar of the cossus.

The sense of *smell* is exquisitely developed in the insect tribes. No sooner has an animal fallen, from age or sickness, even on the loneliest and most barren moor, where perhaps no vestige of insect life was previously perceptible, than troops of flies and carcass-eating beetles assemble from every quarter, led by the emanation of the tainted air.

It was in truth the influence of the sense of smell that in ancient times no doubt gave rise to so many erroneous ideas regarding the origin of insect life. Every animal body in a state of decay being seen to present a crowd of small larvæ or worms, these were regarded as the *produce* of corruption, whereas they resulted naturally, and according to the usual course, from eggs previously deposited by parent flies or beetles, which had been attracted by the putrid effluvia. It is not two hundred years since Redi proved for the first time, by conclusive experiments, that this was true. It is also known that bees will discover and hover around a box containing honey, though their prized treasure is screened from sight; and both flies and beetles are so affected by the perceptions of this sense, that even their peculiar and all but unerring instincts are occasionally deceived by its influence. They will deposit their eggs on plants which are characterized by a fœtid smell (for example, on the *Phallus impudicus*), misled by the resemblance of their flesh-like odour, which the experience of the sense of sight cannot rectify.

The scent of many flowers is cadaverous, and is thus the means of assembling around their deceptive petals numerous insects which feed on putrid matter. It is thus that the spathes of the *Arum dracunculus*, and the corolla of the *Stapelia variegata*, are frequently found covered by Silphæ, flesh-flies, and other species, which not only attempt to feed upon them, but also deposit their eggs in what they conceive to be a fitting station. But the seat of this indispensable faculty is likewise still involved in obscurity. On a subject so difficult of solution, and which can only be solved by a consummate knowledge of anatomical structure, viewed in relation to the uses of physiology, it would not become us to offer an opinion, or do more than report the sentiments of those who are necessarily more experienced than ourselves. Many agree with Dumeril in maintaining that in insects the sense of smell is effected, as among the higher animals, through media in very intimate connection with the process of respiration; in other words, that either the *tracheæ* or stigmatic openings are the seat of its exercise. Others again suppose, that for the exercise of so important a function, a more special and concentrated organ is required; and proceeding upon the analogical relation of mere position, they regard the antennæ as its seat. These receive the first pair of nerves, and so far correspond to the olfactory organs of the higher animals, which are likewise connected with the brain by means of the first pair. The question is one which is extremely difficult of determination, especially in reference to the singular experiments of Huber on bees, which go far to prove that the sense of smell, at least in these hymenopterous species, is placed in the cavity of the mouth.

Christian maintained that insects exercised the sense of smell in relation to distant objects through their antennæ, and in regard to near ones by means of their palpi; while Comparetti imagines that in the different tribes of insects different instruments are subservient to that end. Cuvier, at least in his earlier works (and we are not aware of any recorded change in his sentiments) favoured the opinion already alluded to regarding the respiratory organs. "As the organ of smell," he observes, "in all animals which respire air, is situated at the entrance of the organs of respiration, the most probable conjecture that has been proposed respecting its seat in insects, is that of Baster, since revived by several naturalists, who placed it in the mouths of the tracheæ or air-tubes. In addition to the reasons hitherto stated in support of this opinion, we may observe that the internal membrane of the tracheæ appears very well calculated to perform this office, being soft and moistened, and that the insects in which the tracheæ enlarge, and form numerous or considerable vesicles, are those which seem to possess the most perfect sense of smell. Such are the Scarabæi, flies, bees, &c. The antennæ, which other anatomists have supposed to be the seat of smell in insects, do not appear to us to possess any of the conditions for that organ."[1]

---

[1] *Leçons d'Anatomie Comparée*, sect. 14.

Huber's experiments, undertaken with a view to ascertain the seat of smell in bees, consisted in presenting successively to all parts of their bodies a hair pencil dipt in oil of turpentine, an article which they particularly abominate. When made to approximate the head, trunk, or abdomen, it produced no particular effect, and the odour appeared to be equally disregarded by the antennæ and proboscis. But when he brought the point of a fine hair pencil saturated in the oil almost into contact with the cavity of the mouth, above the insertion of the proboscis, the bee started back in an instant, quitted its food, clapped its wings, and would have taken immediate flight had not the pencil been removed. A repetition of the experiment produced the same signs of discomposure; and similar results, but more prompt and sure, followed the use of oil of marjoram. The indefatigable Genevese observer then stopt up the mouths of several bees with paste, which soon became comparatively hard and dry. In this state they were quite insensible to those odours which had previously produced such painful effects.[2]

Mr Kirby maintains an opinion different from any we have yet alluded to, though more allied to the last than to the others. As the nose of an insect evidently corresponds with the part so named in the Mammalia, not only in its situation, but frequently in its form, and as a constant connection may be observed to obtain between the senses of smell and taste, he felt convinced in the first place that the argument from analogy was wholly in favour of the nose, or anterior portion of the head formerly mentioned under that name. The common burying beetle (*Necrophorus vespillo*) is an insect remarkable for its extreme accuracy and acuteness of smell. While examining the nose of this insect, Mr Kirby observed in the middle of its anterior part a subtrapezoidal space, as it were cut out and filled with a paler piece of a softer and more membranous texture. On dividing the head horizontally, he perceived beneath the nose, and partly under the space just mentioned, which he calls the *rhinarium* or nostril piece, a pair of circular pulpy cushions, covered by a membrane transversely striated with beautifully fine lines. These are what our learned author regards as the organs of smell, and he noted that they remained distinctly visible in a specimen which he had had by him for more than fifteen years.[3]

Hearing is perceptibly acute in some insects, and of more doubtful existence in others. The frequent and various sounds to which many species give utterance have been adduced in proof of their being endowed with this perception; for we cannot but suppose that the shrill voice of the grasshopper, and the evening song of the cricket, are subservient to some essential end, which they cannot well be if unheard by their blythe companions. The small wood-devouring beetle called the death-tick (*Anobium*), answers its neighbour's call as regularly as a cock crows a response to its pugnacious rival; and Derham, when he kept these insects in captivity, by imitating their tiny call, could make them click when he pleased. What is called the voice in insects is usually produced by the friction of certain hard and horny parts of the limbs upon some other portion of the body of a like consistence. In others it is effected by a rapid vibration of the wings; and a few beetles seem to give utterance to a shrill and sometimes plaintive cry by rubbing the terminal segments of the abdomen against the curved points of the elytra. This power of voice, as we call it for want of a better name, is often possessed by the males alone; and as it is used as a call of love in spring and summer (most obviously so among the Cicadæ), we infer the sense of hearing in the females of that family, and consequently in the class of insects.

Brunelli kept some large green grasshoppers (*Acrida viridissima*) in confinement. They used to sing all day in a closet, but ceased when any one gave a rap upon the door. He learned by degrees to imitate their chirping call. At first a few of the boldest would answer him, and then gradually the whole band would strike in and sing with all their might. On one occasion he inclosed a male in his garden, and gave the female her liberty; but no sooner did the husband begin to solace his captivity with a song than his quondam partner recognised the accustomed voice, and flew towards him without delay.[4] In relation to this subject Dr Wollaston makes the following curious observation. "Since there is nothing in the constitution of the atmosphere to prevent vibrations much more frequent than any of which we are conscious, we may imagine that animals like the *Grylli*, whose powers appear to commence nearly where ours terminate, may have the faculty of hearing still sharper sounds, which at present we do not know to exist; and that there may be other insects, hearing nothing in common with us, but endued with a power of exciting, and a sense that perceives, vibrations indeed of the same nature as those which constitute our ordinary sounds, but so remote that the animals who perceive them may be said to possess another sense, agreeing with ours solely in the medium by which it is excited, and possibly wholly unaffected by those slower vibrations of which we are sensible."[5]

The precise position, however, of the organ of hearing in insects has not been determined with precision. In the Crustacea it is found at the base of the large antennæ; and Latreille has satisfied himself of its existence in a similar situation in an orthopterous insect called *Gryllus lineola*. Mr Kirby is of opinion that the *primary* use of the antennæ is to exercise a function analogous to that of hearing, and Mr Rennie entertains a similar sentiment.

The sense of *sight* is too obvious in this class to require demonstration. The eyes of insects are, however, of a very different nature and construction from the exquisitely formed visual organs of the higher tribes. They consist of two kinds, the *composite* and the *simple*. The latter, known under a certain form likewise by the name of ocelli or stemmatic eyes (*stemmata*), are sometimes wanting, sometimes co-existent with the others.[6]

[6] What Messrs Kirby and Spence name *conglomerate* eyes do not essentially differ from simple eyes, collected together in a compact bundle. They occur in *Lepisma*, and many Myriapoda.

Internal Structure.

The composite eyes generally form, as it were, the lateral portions of the head. They are either entire, notched, or even occasionally so completely divided by a little corneous stalk, as to exhibit (for example in the genus *Gyrinus*) the appearance of a pair on either side. In other respects their forms are extremely variable—their surfaces more or less convex. These compound eyes are composed externally of a hard and transparent membrane (softer in the dipterous tribes), which presents an infinity of small hexagonal surfaces, disposed with the most exquisite regularity. This peculiar structure prevails equally on the concave or internal, as on the convex or external surface. The structure and composition of the eyes of insects have been carefully studied and explained by Leeuwenhoeck, Swammerdam, Cuvier, and more lately and laboriously by Marcel de Serres. We shall here avail ourselves of the *resumé* given by M. Victor Audouin.[1] In the eye of an insect we observe, 1*st*, a cornea (convex in proportion to the carnivorous habits of the species), transparent, hard, thickish, generally encased in a groove of the head, and exhibiting many thousand regularly disposed, hexagonal facettes, each of which is in itself a perfect eye. These are sometimes so numerous that not fewer than 34,650 lenses have been counted in the head of a butterfly, and the coleopterous genus *Dynastes* of Macleay is supposed to be still more wonderfully and exuberantly supplied. 2*d*, An opaque, slightly liquid matter, variously coloured, frequently deep violet or black, but sometimes red or green, tenaciously adherent to the inner face of the cornea, and distinct from the deep-black varnish of the choroid. It is by no means rare to observe various colours united in the same eye, which then appears beautifully mottled, as in many species of the orthopterous, neuropterous, and dipterous orders. These tints, however brilliant in the living state, speedily vanish after death. They are always owing to this peculiar coating of the cornea. 3*d*, A true choroid, covered by a dark varnish, which may be regarded as a *pigmentum nigrum*. The lynx-eyed Swammerdam failed to distinguish this coating from that of the cornea; but, in the opinion of Marcel de Serres, it is really different. The choroid and its pigment do not always exist in insects. They are wanting in the *Blattæ*, and in all the lucifugous or light shunning species, such as those of the genera *Blaps*, *Tenebrio*, and *Pedinus*. In these cases, it has been remarked that the covering of the cornea is much deeper than usual. The choroid membrane is fixed by its circumference to all the margin of the cornea, of which it follows the contour, and is intimately connected with the tracheæ, which are there so numerous. 4*th*, Air vessels which play an important part. They take their rise from larger trunks which are situated in the head, and form around the eye a circular trachea, which sends forth an infinity of branches, producing by bifurcation a number of isosceles triangles. These triangles, of which the base is outwards, are placed around the optic cone, and receive, in each angular interval which separates their summits, a nervous filament, which traverses the choroid, and reaches the external surface of the covering of the cornea. The assemblage of tracheæ and nervous threads forms at the circumference of the eye a peculiar kind of network, of which the aspect is beautiful to look upon. The tracheæ themselves are so abundant on the choroid, that that membrane appears to be composed of them; and it may also be noted, that in those genera in which the choroid is wanting, the circular trachea is likewise absent.[2] 5*th*, Nerves arise from a principal branch which, after proceeding immediately from the brain (or upper ganglion), is either encompassed by a little circular trachea, or traverses the fibres of the abductor muscle of the mandibles. This branch soon augments in volume, and forms a kind of cone more or less extended, of which the base is towards the transparent cornea. Numerous nerves proceed from that base, mingle with the tracheæ of the choroid, traverse both that membrane and its pigment, penetrate the lining of the cornea, and finally terminate each on a facette of the transparent cornea, so that the nervous filaments are thus immediately in contact with the light, which reaches them after having traversed only the last-named organ. This disposition of the nervous threads, which thus constitute as many small retinæ as there are facettes in the cornea of the eye, is very distinguishable in *Libellula*, *Truxalis*, and *Gryllus*. The eyes of insects, then, contain no humours properly so called,—neither vitreous nor crystalline,—and vision is consequently much more simple with them than with the vertebrated tribes, in which the nerves are placed deeper in the eye, and do not receive the rays of light till these have passed through media of different densities.

The simple or *stemmatic eyes* of insects are usually three in number, and are placed on the crown of the head, between the genuine organs of sight, from which their structure differs. In spite of their extreme minuteness, Marcel de Serres has succeeded in detecting the following component parts. 1*st*, A transparent cornea, formed by an external membrane, hard, convex externally, and smooth, that is, exhibiting no appearance of facettes. 2*d*, Of a variously-coloured matter, which lines the internal face of the cornea, but which is perhaps not essentially distinct from the varnish of the choroid. It varies in colour, being almost always black in Hymenoptera, usually whitish in Orthoptera, and, in many caterpillars, yellow, red, or green. 3*d*, A kind of choroid, rather thick, more extended on the surface than the cornea itself, sometimes of a black colour, more frequently red, and occasionally of a peculiar whitish hue. 4*th*, Tracheæ, which do not derive their origin from a circular air vessel, and do not, as it were, constitute the choroid, but appear to be distributed over its surface. 5*th*, Nerves proceeding either directly from the brain or upper ganglion, or from another more considerable nerve or common trunk, according as these simple eyes are separate from each other, as in perfect insects, or closely approached, as among larvæ. In their passage towards the eyes they are attached to the neighbouring parts by tracheæ or air vesicles, and do not appear to present any swelling; they pass between the motive muscles of the different parts of the head, traverse the choroid and its varnish, and expand upon the internal face of the cornea, where they are surrounded by the layer of pigment belonging to that membrane. Thus, on examining the simple or stemmatic eyes of insects, and proceeding from the circumference to the centre, we meet with a transparent cornea,—a pigment, which lines its inner face,—the termination of the optic nerves,—the pigment of the choroid, when distinct from that of the cornea,—and the choroid itself, which frequently rests upon a large trachea. The principal character of these simple eyes consists in this, that each is a single organ, whereas the composite eyes, as the name implies, are formed by the union of many. The one kind is most characteristic of the larva state, the other of the perfect insect; but several orders, even in the last-mentioned condition, possess both organs.

---

[1] *Dict. Class. d'Hist. Nat.* t. viii. p. 554.

[2] Muller and others appear to entertain a different view from that given above. The subject is one of considerable complexity, and our present limits prevent our entering into its various and sometimes contradictory details. We refer the curious reader to a series of papers on the visual organs of insects and Crustacea in the fourth volume of the *Naturalist's Magazine*.

Thus, with few exceptions, the Orthoptera, Hemiptera, Hymenoptera, Neuroptera, and Diptera, possess both simple and compound eyes. Dr Carus however states that the stemmata do not exist either in beetles or butterflies; a most erroneous opinion in regard to the latter, in which they exist universally, although not always detected; and incorrect as to the former, in several of which they have been distinctly seen. They are visible in Gravenhorst's genus *Omalium*, or at least in some of the species;[1] and Mr Kirby found them very conspicuous in *A. Caraboides*, and other Anthophagi. They are wanting in Strepsiptera, Dermaptera, and Aptera.

Although neither Linnæus nor Fabricius, those great masters in the science, gave any explanation of the uses of the stemmata, there can be no doubt that Swammerdam and Réaumur were correct in regarding them as genuine eyes.[2] The French writer supposes that the compound organs have the power of magnifying, and are used for surveying more distant objects, while the simple ones possess little of that power, and are employed on objects close at hand. Blumenbach is also of opinion that the polyhedral eyes are for viewing distant objects, and the simple ones for such as are near.[3] This is in some measure confirmed by the fact, that while most insects in the perfect state have large compound eyes, caterpillars and other larvæ have usually small myopic ones. On the other hand, the Mole cricket (*Gryllotalpa*), a truly subterranean species, is furnished with both kinds. Réaumur's experiments on the visual organs of bees are extremely important in relation to our present subject. He smeared the compound eyes with paint, when the insects, instead of directing their flight towards the hive, ascended in the air till they were lost to sight. He then treated the stemmatic eyes in the same manner, and placing his patients near their hive, they winged their way on all sides among the surrounding flowers, but neither ascended into the air, nor flew far from home. From these experiments it has been supposed that the compound eyes are for horizontal sight, and the stemmatic for vertical.[4] Spix imagines that what we call simple eyes in insects are in fact olfactory organs.[5] Nothing can be adduced in support of a theory so fantastical.

We shall conclude this branch of our subject by observing that some insects are supposed to be entirely destitute of eyes. This is the case, according to Rudolphi,[6] with the coleopterous genus *Claviger*, in which there are certainly no apparent eyes; and Marcel de Serres observes, "un assez grand nombre de larves à metamorphose complète n'ont point d'yeux du tout."[7]

SECT. II.—THE RESPIRATORY SYSTEM IN INSECTS.

Though insects respire air, they do not receive it, like the majority of vertebrated animals, through nostrils or other orifices in the head, but by means of numerous small openings along the sides of the body, and which lead not to lungs, but to a system of air vessels ramified *ad infinitum* through every part of the body. The respiratory organs of this class are composed of *stigmata*, *tracheæ*, and *bronchiæ*. The first, called also spiracles or breathing pores, consist of small perforations of various forms, placed along the lateral portions of the body, and generally incased externally in a small corneous ring, though sometimes pierced in the membrane which separates the dorsal from the ventral surface. These stigmatic openings occur both on the thorax and abdomen, and lead inwards to the tracheæ. Their number varies according to the species, and even in the same species according to the temporary condition of the individual. They are wanting on the second and third segments of the body of the larva; and as it is from these segments that the wings are developed, M. de Blainville has been induced, probably by that circumstance, to regard the organs of flight as reversed and expanded tracheæ. The existence, however, of stigmatic openings on the thorax of the perfect insect simultaneously with the wings, militates against this theory; for if these parts were convertible, would they not be likewise each exclusive of the other?

Parallel with the sides of the body of most insects, and extending its whole length, run two cylindrical tubes, which communicate with the spiracles, and give issue, at points opposite to those organs, to other tubes, the ramifications of which are distributed over all the membranes, penetrate the muscles, and pervade even the legs and wings. They also envelope the dorsal vessel and digestive organs, and demonstrate that the ultimate aim of respiration is assimilation, or the increase and reproduction of organic molecules, by the decomposition of food. The first of these tubes are called the tracheæ, the latter the bronchiæ. This structure, however, cannot be regarded as universal, as in many of the lamellicorn beetles the bronchiæ spring directly from the spiracles, the interior mouth of which is lined by a membrane from which they proceed.[8] But a volume would scarcely suffice to describe the beautifully varied features of the respiratory system in insects. Among those tribes especially which pass their early stages under water, the changes in form and position in these organs cannot be sufficiently admired. Several common species of gnat, the larvæ of which abound during the summer season in all our ponds and marshes, will afford a familiar illustration. When one of these is examined, a singular tunnel-shaped organ, terminating in a radiated point like a star, will be perceived, forming an angle with the penultimate segment of the body. In the interior of this organ is a tube, which conveys the air to the tracheæ, and communicates with the atmosphere by means of several perforations in the centre of the star. The diverging rays of the star suspend the animal at the surface of the water, with its head downwards, till it wishes to descend. It has no sooner assumed the pupa state, than the respiratory tail disappears, and the insect (still an inhabitant of the water) then breathes through two projecting horns, each resembling a little cornucopia, which proceed from the upper part of the trunk. Ere long the skin of the pupa bursts asunder, and the perfect gnat, or winged insect, makes its appearance, with neither caudal nor thoracic appendages, but breathing by means of numerous lateral pores (the stigmata above mentioned), after the usual manner. The *rat-tailed worm* in this respect is still more extraordinary. In the larva state it breathes through a tail formed of retractile tubes, like a telescope, and capable of being extended many times the length of the body. This also terminates in a star-like process, which, when viewed in a strong light, forms a perceptible dimple on the surface of the water; and as the body of the insect lies in the mud below, the tail is contracted or extended according to the varying depth of its stagnant habitation. On assuming the pupa state, in which it is no longer an aquatic animal, the respiratory tail is cast off, and its function performed by four horns, which spring from the upper part of the thorax. It afterwards becomes one of those bee-like flies so remarkable for the rapid vibratory movement of their wings, by which, during calm sunshine, they are often seen suspended in the air like hawks, without any perceptible motion. In this last stage respiration is carried on by spiracles or breathing-pores.

SECT. III.—THE DORSAL VESSEL, OR SUPPOSED CIRCULATING SYSTEM, OF INSECTS.

We shall next endeavour to explain the construction and physiological uses of the organ known by the name of *dorsal vessel*.

The *primary* use of the heart of animals is the elaboration of the nutritive fluid by which the general system is strengthened and sustained; its *secondary* use is to effect the circulation of that fluid, a process by which important changes are produced in its nature or attributes. The dorsal vessel, which corresponds to the heart in insects, certainly effects the primary purpose; its performance of the secondary one is, as we shall see, a matter of greater dubiety.

When an insect is dissected with due precaution from its inferior surface, and we remove the nervous system, which first presents itself, and then the intestines and other viscera, we shall observe running along the back, a peculiar vessel, of which the most obvious powers are those of contraction and dilatation. It is of a cylindrical form, narrowed at either end, and extends from the head to the anal extremity. This constitutes the *heart*, frequently so called, of the class of insects. A closer examination shows that it is composed of two membranes, one internal and muscular, the other external and cellular, and pervaded by a close interlacement of tracheæ or air-vessels. When opened, its interior presents a transparent coagulable liquid, which dries rapidly, and then exhibits the aspect of gum, of a colour seldom deeply defined, but sometimes greenish, orange yellow, or sombre brown. Masses of fat frequently surround this vessel, and partake of the tint by which it is pervaded. If, as Marcel de Serres has noted, the *dorsal vessel* (for so this organ is often named) were a genuine heart, or centre of a circulating system, it would be necessarily open at one or other of its extremities, and would present vascular ramifications in certain points of its extent. But, according to the minute and laborious investigations of the last-named author, no such openings are observable. The same view was taken by Swammerdam; and Lyonnet, so unrivalled in his examination of the structure of insects, was foiled in his attempts to demonstrate the ramifications of the dorsal vessel. Comparetti no doubt took another view of the subject; and if the assurance of his readers was equal to his own, less suspicion would exist of the possibility of his having mistaken biliary for sanguineous vessels.

Anatomists, however, are greatly divided in opinion regarding the essential nature of this organ. It has been dissected and injected by Marcel de Serres in a variety of species; but in none could he discover its divisions or ramifications. Even when he removed it entirely from the insect, no drop of the liquid which it contained was observed to escape, which he thinks it must have done on the cutting away of open vessels during dissection, had these existed. The *beating* of this dorsal vessel was not explicable, otherwise than by the contraction of its tissue, or the movement of the fluid which it contained; and such movement was not itself conceivable except in the case of circulation, which the alleged closure and non-division of the organ forbade us to suppose. Its contractions also appeared irregular, and scarcely ever isochronic; that is, the same number of pulsations, if they may be so called, did not take place in an equal time. They varied singularly in different species. Thirty-six per minute were counted in the caterpillar of the *Pavonia Major*, eighty-two at least in grasshoppers, and a hundred and forty in one of the ground bees. While endeavouring to discover the cause of these contractions, Marcel de Serres came to the conclusion that they bore a relation, 1*st*, to the quantity of adipose tissue by which they were surrounded; 2*dly*, to the energy of the muscular fibres which were inserted on the vessel, and were the means of fixing it to the rings of the abdomen; 3*dly*, to the number of tracheæ or air conduits by which it was supplied. He was not of opinion that the nerves exercised any strongly marked influence on these contractions, although we know that special nerves are directed to the dorsal vessel. The fact, however, which he deemed the most clearly established, was the influential action of the muscles. When any of these were removed, the pulsations became less frequent,—on a farther removal they still diminished; and when the muscles were almost all withdrawn, the pulsations ceased. The appropriate function of this disputed organ, according to the last-named author, is the secretion of fat. Baron Cuvier also denies to it the character of a genuine heart.

Meckel and Herold, on the other hand, regard the dorsal vessel as a heart, and they conceive that the use of its movement is to agitate the fluid contained in the cavity of the insect's body; but they do not admit the existence of posterior or anterior openings for the reception or rejection of that fluid. It is long since Lyonnet informed us that it contained a gummy matter of an orange colour; and some recent observations have led Latreille to admit the existence of certain very minute accessory vessels. In addition, however, to the fact that this circulation must be extremely partial, insects would still greatly differ in that respect from the Crustacea, inasmuch as the blood does not return to the heart. Herold is of opinion that the triangular muscles of the dorsal vessel serve for its dilatation, while the systole movements are effected by the muscular fibres, which form the proper tunic. Straus is also of opinion that the dorsal vessel is the true heart in the class of insects, and that it serves, as in the higher animals, as the motive organ of the blood, which, however, instead of being contained in vessels, permeates in the general cavity of the body. According to his views, it terminates anteriorly by a single unramified artery, which conveys the blood to the head, where it pours it out, and from whence it returns again to the abdomen, to re-enter the dorsal vessel. He thus limits the circulating system of insects to a single artery without branches (there are not any veins); and he combats the sentiments of Herold regarding the muscular nature of the wings of the heart, which, he maintains, are only simple fibrous ligaments, by which it is maintained in its proper place. The heart itself, that is, the abdominal portion of the vessel, he describes as divided interiorly into eight successive chambers (as in the common cockchafer, *Melolontha vulgaris*), separated from each other by two convergent valvules, which permit the transmission of the blood or circulating fluid from behind forwards, and from one chamber to another, up to the artery which conducts it to the head, but prevent its retrograde motion. Towards the lateral and anterior portion of each chamber are two transverse fissures, which communicate with the abdominal cavity, and through which the blood contained in the latter enters the heart. Each of these apertures is provided internally with a little semicircular valve, which presses on it during the systole of the organ. When the posterior chamber dilates, the fluid contained in the abdominal cavity penetrates into it by the transverse fissures, called *auriculo-ventriculaires* by M. Straus. When the chamber contracts, the blood, unable to return into the abdominal cavity, forces the *inter*-ventricular valve, and passes into the second chamber, which dilates to receive it,

Internal Structure.

along with an additional quantity which enters by the true auriculo-ventricular openings. The second chamber then contracts in a similar manner, and forces the fluid into the third, which at the same time also receives a supply from the lateral openings; and thus the blood is forced from one chamber to another by successive contractions, till it reaches the artery. These are said to constitute the movements so distinctly perceptible through the dorsal skin of many caterpillars.

Mr Bowerbank has recently published some observations on the circulation of the blood in insects.[1] The instance detailed was that of the larva of an Ephemera (*E. marginata*). In fixing the insect for examination (under water), especial care must be taken not to compress the body, which impedes or interrupts the circulation of the lateral vessels, and that of the tail, legs, and antennæ. When the larva is fixed, with its dorsal aspect towards the observer, a truly beautiful sight is said to present itself. The blood, abounding in flattened oat-shaped particles, will be seen circulating in every part of the body, not in a continuous stream, but at regular points, in accordance with the pulsations of the great dorsal vessel. The latter, which is of great comparative magnitude, extends nearly the whole length of the body, and is furnished at regular intervals with double valves, nearly equal in amount to the segments of the body. Both above and below each of these sets of valves there is a pair of irregular-looking appendages, which are probably nervous ganglions, auxiliary to the motions of the vessel, but so extremely translucent as to be scarcely definable in their form, even through the medium of the highest power which we can apply. The action of the valves is singularly interesting. While in their greatest state of collapse, the point of the lower valve is seen closely compressed within the upper one. At the commencement of the expansion of the artery, the blood is seen flowing in from the lateral aperture, and at the same time the stream in the artery commences its ascent. When it has nearly attained its greatest state of expansion, the sides of the lower valve are forced upwards by the increased flow of the blood from the section below the valve, the lateral openings are closed, and the main current of the blood is projected through the two valves. The structure of the upper valve appears to consist of a duplication inwards and upwards of the inner coat of the artery; that of the under, of a contraction and projection of the like parts of a portion of the artery beneath, so as to come within the grasp of the lower part of the valve above it. The exterior portion or continuation of the artery is perceptible in the form of an exceedingly fine and transparent membrane. The so-called blood does not appear to be confined within any specific vessels prior to its entering the lateral openings just mentioned, because, as soon as they expand, the particles are seen converging towards them. The whole of the fluid received throughout the course of the dorsal vessel is conveyed to the extremity of the anterior part of the body, where the vessel makes a curve inwards, and is lost to view. To all appearance the main current of the blood is now discharged into the cavity of the body, as it is seen pursuing its course downwards in a wide-spreading stream on each side, and beneath the dorsal vessel. As it descends, portions are again absorbed by the valves of the large vessel, while at the same time smaller vessels pass down each side of the body, and convey another portion of blood to the lower extremity. These lesser vessels have perceptible boundaries, and are certainly not portions of the great abdominal cavity. They communicate at each junction of the segments of the body with that cavity, as a part of the fluid they convey is discharged at those points, to supply the place of what is absorbed by the valves of the dorsal vessel, into the lower end of which they empty their contents. In the caudal extremity the ascending and descending vessels are seen, like vein and artery, to accompany each other, and at the same moment that the fluid passes up the one with the usual pulsatory motion, it descends the other. There is, however, no perceptible pulsation of these minuter vessels themselves, and the motion of their fluids therefore results from the action of the great dorsal heart.

"Next to the larvæ of the Ephemera marginata," Mr Bowerbank observes, "the larvæ of Agrion afford the best view of the blood and its circulation. In all the species of these larvæ I have yet examined, I have found it as nearly similar as possible in appearance to that which we observe in the Ephemera, and in some instances it has afforded even more satisfactory results. The head of this larva is much more transparent than that of the larva of the Ephemera; we therefore have a better view of the circulation of the blood in the head of this insect than can possibly be obtained in the other. In this object the blood is seen rushing like a beautiful intermittent fountain towards the mouth, and dividing right and left into two jets, a portion of each of which flows within a given boundary past the back of the eye, whilst the remainder winds its way through other channels, deep in the side of the head, and returns again into the body. The antennæ of this insect also afford another beautiful instance of the circulation being carried forward within well-defined vessels. They are each composed of six joints, up four of which the blood is seen to take its course; and turning round the extremity of the fourth joint, it returns by a distinct vessel into the head. In the leg, likewise, the circulating fluid and its vessels are clearly and distinctly to be traced, even to the very extremity of the tarsus, where, as in the antennæ, the particles of the blood are seen to descend on the one side of the leg, and, turning the extreme point, to return up the contrary side to the one by which they come down. I regret much that I have not yet had an opportunity of examining the Ephemera in its perfect state; but in two species of Culex, one of which was first observed and brought to me by my friend Mr Tulley, I have seen the great dorsal vessel performing its functions in a manner similar in every respect to its appearance in the larvæ of Ephemera, Agrion, &c. &c.; but, from the body of the fly being more opaque than that of the larvæ, and nearly covered with its striated scales, neither the valves nor the particles of the blood could be detected. On another occasion, after having carefully cleared the wings of Phlogophora meticulosa of their coloured scales, both Mr Samouelle and myself clearly saw a fluid pass down the side of one of the principal ribs of the wing. We may therefore, I think, fairly conclude, that the circulation is carried forward in the perfect insect as well as in the larva, although, perhaps, not with so much vigour as when young and growing."[2]

The writer whose observations we have just quoted, inclines to the opinion that a much greater portion of the circulation than we can clearly define is carried on within special vessels, as the blood may be frequently seen flowing in curved and other lines, as if confined within very narrow limits. These streams, however, are generally so deeply seated amidst the muscles and intestines as totally to prevent their boundaries from being clearly seen. The blood itself is in fact a perfectly colourless and transparent fluid, rendered visible only by its containing a number of oat-shaped particles; and even the great dorsal vessel cannot be seen distinctly but by means of a glass of great power, and, under the most favourable circumstances, exhibits defined limits with certainty only when in motion. A singular coincidence is observable between the flattened particles of the blood of insects, and the circular double concave plates in that of man, namely, that the former, in common with the latter, assume a globular form immediately on coming into contact with water.[1]

---

[1] *Entomological Magazine*, No. III. p. 239.

[2] *Ibid.* p. 242.

The reader will be able to judge, from the preceding notices, of the diversified opinions still entertained regarding the circulation of the blood in insects. We shall conclude with a short account of Dr Carus's observations, which many consider as the first of a satisfactory and conclusive nature on the subject. Mr Spence, the accomplished coadjutor of Mr Kirby, having had the advantage, at a pretty recent period, of witnessing some of the most striking facts on which the Dresden physician rests his views, transmitted an account of them to an English periodical. "The first insect," he observes, "to which Dr Carus directed my attention was the larva of *Ephemera vulgata* (or an allied species), in which, near to the branchiæ, and parallel with each side of the body, was very distinctly visible a constant current, towards the tail, of oblong globules, swimming in a transparent fluid, propelled with a regular pulsating motion; and in cutting the body of the larva across, near the tail, these globules were most plainly seen pushed out of the divided vessels in a distinct mass, which increased at each pulsation. I cannot express the pleasure which it gave me to see thus clearly this ocular demonstration of one of the most important physiological discoveries of modern times; and my gratification was heightened by the next object which Dr Carus placed before his microscope, viz. a specimen of *Semblis viridis*, in which precisely the same phenomena, but if possible more clearly, were seen in the nervures of the wings, and in the antennæ, in both which the constant current of globules was most apparent; and in the former, the sudden turning of these globules at the apex of the wing, out of the exterior nervure, into a central one, with which it joins and forms an acute angle, was equally curious and striking. On cutting off the end of the antennæ, precisely the same emission of globules (which soon assume a greenish tint) took place as in the former case, forming a mass which was increased with a sudden gush at each pulsation."[2] The chief point to be attended to in the manipulation of these microscopic experiments, is to place the specimens on the slip of glass, in a drop of pretty thick gum water, which confines their too agile movements, without affecting the transparency of the medium.

SECT. IV.—OF THE ADIPOSE TISSUE OF INSECTS.

Insects are abundantly supplied with an adipose substance or fatty matter, which may be mentioned in this place with the more propriety, as many consider it a secretion from the dorsal vessel. It is spread over the viscera and in the splanchnic cavities; and although its aspect varies, it seems to consist essentially of membranous woofs, in some cases divided in shreds, in others spread over the intestines and against the sides of the abdomen, and containing pouches filled with a homogeneous pulpy matter, sometimes in an oily condition, and offering all the characters of grease. Much more of it is observable among larvæ than in perfect insects, and this observation leads us to a knowledge of its use. It is particularly plentiful just before an insect is about to undergo its metamorphosis; and as it almost entirely disappears on the completion of those signal changes, we naturally conclude that it has served in the production or development of the newly acquired organs. This is rendered the more probable when we consider that, during the intermediate or nympha state, the insect abstains from food, and is therefore necessarily dependent on some internal reservoir. It is analogous, in fact, to the store of fat which is known to pervade the system of hybernating animals before they consign themselves to their winter sleep.

In regard to the nutrition of insects, our opinions must be in a measure regulated by the sentiments which we may adopt as to the functional uses of the dorsal vessel. We need scarcely observe, that in all the higher animals, and in most of the invertebrated tribes, nutrition is effected through the medium of the blood, which, propelled by the heart, circulates through the entire system, and reaches every organ, after having been submitted to the action of the air in lungs or gills. Cuvier thinks it is carried on among insects by imbibition. The alimentary canal elaborates a fluid which transudes through its coats, and flows into the cavity of the body. There the various organs, such as the muscles, the nerves, and many secreting vessels, absorb from that fluid nutriment, whatever molecules are best adapted to their purposes. Those who look upon the dorsal vessel as a true heart, which dispenses a circulating fluid to the remotest ramifications of the wings and tarsi, will place less confidence in this particular view. However, it is certain that the secreting vessels are characterized by a structure entirely appropriate to the functions which we have just assigned them, their surface being obviously furnished with numerous pores or small absorbent mouths.

SECT. V.—THE DIGESTIVE SYSTEM OF INSECTS.

The digestive system in insects naturally forms the next subject of consideration. The earliest, most general, and perhaps the only indispensable function of animal life, is that of nutrition. But its materials are so different, and their modes of reception so various, that the exercise of this function by no means necessitates the existence of a mouth, a stomach, or an alimentary canal; for an increase of parts may be effected even through the medium of imponderable or elastic fluids, and by imperceptible and superficial pores.[3] The digestive organs of insects are however in general rather complicated, and a great variety of parts are brought into action. The more external portions, or those of the mouth, have been already described. We shall therefore at present confine our observations to the different portions of the *intestinal canal*, and the *biliary* and *salivary vessels*.

It is natural to suppose that, in a class so extensive and varied as that with which we are now engaged, a corresponding diversity must exist in the form, development, and number of the parts which constitute the intestinal canal. It is always, however, so far tubular, and open at either end; but in some it is straight and of the length of the body; in others it is bent and longer than the body; while in many it is tortuous, or twisted on itself in numerous convolutions, and consequently of great extent. In general, its length corresponds in a certain measure with the nature

---

Internal Structure.

of the aliments; such insects as feed on vegetable matters having a longer, and such as feed on animal substances a shorter canal. In some it is of equal diameter throughout; in others the breadth of special portions varies; and there are many dilatations and restrictions, known by various names. It even differs greatly in the same species, according as the individual exists in the larva or imago state.

The texture of the intestinal canal in insects is not the same in all parts of its extent; but on a careful examination it is found to exhibit throughout three tunics, more or less distinctly marked. Of these, the first is external, with a membranous aspect; the second is of course intermediate and muscular, with its fibres diversely directed; the third is internal and mucous. In its more complicated state it exhibits the following parts: 1*st*, a *pharynx*; 2*d*, an *œsophagus*; 3*d*, a *crop*; 4*th*, a *gizzard*; 5*th*, a *chylific ventricle*; 6*th*, *intestines*, which may be considered in subdivision as the small intestines, the great intestine or cæcum, and the rectum. The following may be regarded as the usual process of transmission. The mouth, having seized and chewed the food, transmits it to the pharynx, into which salivary vessels sometimes open. It then passes into the œsophagus (of which the muscular nature occasionally produces by its action a peculiar impression), and is next transmitted to the crop, which converts it into a homogeneous pulp. This is introduced into the gizzard, of which the sides, being armed with teeth, complete its trituration. In the form of a kind of paste it is now received by the chylific ventricle, where it undergoes the action of the bile, is converted into chyle, and thus supplies the nutritive fluid, which, passing through the coats of the ventricle, spreads over the splanchnic cavity, and pervades the whole of the organs. The residue is received by the small intestine, then by the great intestine, in which it remains for some time, and finally by the rectum.

The *pharynx*, which is sometimes rather difficult to distinguish as a distinct feature, is placed at the bottom of the mouth, and may be regarded as an anterior dilatation of the œsophagus. Two pieces, very apparent in certain Hymenoptera, called the *epipharynx* and the *hypopharynx*, seem to restrict and protect its entrance.

The *œsophagus* is a conduit varying in length, which traverses the prothorax, and sometimes extends beyond it; but it is occasionally so short as scarcely to pass beyond the region of the head. Its structure is musculo-membranous, and it opens into the crop, or, if that part is wanting, into the gizzard, or, if the latter is also absent, into the chylific ventricle. It is around the origin of the œsophagus that the nervous system, as formerly described, constitutes a ring, by sending forth two branches which unite on the inferior face of the body.

The *crop*, which is by some called the stomach, is essentially nothing more than a dilatation of the œsophagus. It is often difficult to detect, is sometimes entirely wanting, and may be observed to vary greatly even in two individuals of the same species. Exteriorly it does not differ much from the gizzard, but its interior never presents those corneous pieces which in the latter serve the purposes of trituration. Its position bears some analogy to that of the crop of birds, from which circumstance it has probably derived its name. Its texture is simply membranous, or slightly muscular when its development is considerable, and in that case it is not rare to observe certain folds or fleshy columns and deeper lines, which give it something of a ribbed appearance. These folds, prolonged in the interior, frequently constitute a kind of valve. It is in this crop that bees contain their honey prior to their disgorging it, and it likewise serves as the reservoir of that black and often fetid fluid which many insects allow to flow from their mouths when they are seized. The form of the crop differs in the various species; and even in individuals of the same species, according to its state of repletion or vacuity, it assumes an ovoid, rounded, or pear-shaped appearance. In some orders of insects it is greatly developed, and very muscular; and in certain cases, instead of lying in the same direction with the intestinal canal, it forms with it an angle more or less acute, thus constituting a lateral pouch varying in extent and form.

The *gizzard* follows the crop. Its existence is not constant, and its essential character consists in its singular internal structure, which is furnished with moveable portions of a horny texture, provided with ridges or bristles pointed in all directions, in the form of combs or brushes. The principal portions are more or less numerous, and form by their union a kind of valvule at the orifice of the chylific ventricle, into which they permit nothing to enter but what has been previously reduced to a state of tenuity. This very singular triturating machine, as we may call it, exists among both the herbivorous and carnivorous kinds. It recalls to mind the aspect of the stomach among the crustaceous tribes. Externally it greatly resembles the crop, and indeed can scarcely be distinguished from it otherwise than by its internal structure.

The *chylific ventricle*, which corresponds to the part named *duodenum* by Marcel de Serres, and *stomach* by Ramdhor, is a very constant organ among insects, although its form and character are extremely various. It is here that the pulpy food, mixed with specially elaborated fluids, is converted into chyle. One of its most constant characters is the insertion on a kind of circular pad more or less developed, of at least one extremity of the biliary vessels. Its texture is soft and delicate, and capable of varying its capacity by extension. Its form is generally cylindrical, although it sometimes undergoes dilatations and restrictions in its course. In some rare instances, detailed by M. Dufour, it is bilobed or bifurcated at its commencement, the preceding part of the alimentary canal being inserted in the angle of the furcation. It presents several other occasional and very curious characters, but it is in general straight, and but rarely exhibits a limited number of convolutions. It is not garnished interiorly with triturating organs, either muscular or corneous; but it is furnished with a valvule at the point of union with the intestine. One of its most curious characters consists in its being sometimes villous on the surface, that is, covered by a quantity of little tubes, named *villosities* by Cuvier, and *papillæ* by Dufour. These are a species of tubes or purses, somewhat resembling the fingers of a glove, and opening into the ventricle. Their functional uses are differently construed by physiologists. Cuvier inclines to think that they draw from the abdominal cavity a gastric fluid, which they pour into the ventricle to aid digestion. Marcel de Serres partakes of the same opinion, and regards these papillæ as the superior hepatic vessels. Dufour, however, does not consider them as analogous to the biliary vessels, but as culs-de-sac, which receive the alimentary fluid, and, after its conversion into chyle, transmit it to the abdominal cavity. That able anatomist has recognised in their interior a brownish matter, quite analogous to what is contained in the ventricle itself. They do not differ greatly as to form, but a great variation occurs in regard to number and disposition. Sometimes they exist in great numbers throughout the whole extent of the ventricle, sometimes they are fewer in number, and confined to a limited portion. Insects belonging to the orthopterous order have but few of these papillæ, but they are greatly developed, and inserted on the anterior part. In other instances the papillæ are entirely absent; and the ventricle is then smooth, or occasionally exhibits depressed lines, which divide it transversely into so many little bands. The presence of

Internal Structure.

these papillæ cannot be regarded as a constant character in any group, for we find them absent or present in different insects of the same family, without any known or assignable cause. They occur indiscriminately among carnivorous and herbivorous species; but it is among the coleopterous tribes that they show themselves most frequently, and under the most characteristic forms.

The *intestines* constitute an extended portion of the canal. They receive the alimentary matters after they have been digested in the chylific ventricle, and extract by their action whatever nutriment remains. Their absorbent powers, however, as alimentary organs, are probably confined chiefly to their upper portion. They consist of a *small intestine*, a *great intestine*, and a *rectum*. The small intestine of course proceeds from the ventricle, and is in general narrow, with an equal diameter throughout, although it is sometimes swollen or pursed in the course of its extent. It is of various length, and makes numerous circumvolutions in the interior of the abdomen, after which it borders with the great intestine. The latter, called also the *cæcum*, consists of a swelling or enlargement, usually ovoid and smooth, but not unfrequently also covered by plaits and little muscular rib-like bands, more or less projecting. It is dilatable, and in some cases is swollen beyond measure, especially among certain aquatic tribes, such as the *Dytisci*. In these, as detected by the skilful eye of M. Dufour, the cæcum is no longer placed in the direction of the intestinal canal, but is thrown to one side, and furnished with a vermicular appendix, spirally twisted. It becomes inflated with air at the will of the insect, and thus seems to act the part of a swimming bladder. Other modifications of this organ have likewise been observed, into the detail of which we shall not here enter. The rectum is a muscular tube, in general of no great extent.

We shall next devote a few lines to the *biliary vessels*. That peculiar fluid called bile seems equally indispensable to the digestion of insects as to that of the higher animals, but the organ which secretes it is very different. In the former class it has no longer the appearance of a gland, but consists of more or less numerous vessels, of variable length, fixed for the most part by a single extremity, but not unfrequently by both ends, to the intestinal canal, and floating as it were in the abdominal cavity. These vessels are often rolled on themselves, and interlaced by numerous tracheæ and slender nervous filaments. They are never wanting in insects, and they exist equally in the larva state as in the perfect condition. They are delicate tubes, composed of a thin and pellucid membrane, on which certain transverse foldings produce a somewhat varicose appearance. They contain a liquid, sometimes limpid and colourless, but usually varying from yellow to brown. It is bitter, and exhibits all the characteristics of bile. The vessels themselves vary in amount from two, four, six, to an almost countless number. Their mode of insertion exhibits some remarkable variations, which however may be reduced to two great divisions: 1*st*, where the insertion takes place upon the ventricle alone; 2*d*, where it takes place upon the cæcum likewise. The first of these divisions offers two classes; sometimes the vessels are inserted only by one extremity, while the other is free or floating; sometimes they are fixed by both ends, and form so many arches. In the latter case they are few in number, and each arch may be regarded either as a vessel strongly curved towards the two points of insertion, or may be looked upon as composed of two vessels exactly anastomosed at their extremities. A coleopterous insect belonging to the genus *Donacia*, described by M. Dufour, was observed to possess a ventricle provided at once with arched vessels and with such as were free at their extremity. Such a combination connects, as it were, the characters which principally distinguish the first great division. The second great division above alluded to never presents us with any vessels that are free or unattached at one extremity. They form a complete arch from the ventricle to the cæcum, and scarcely present any particular character, except that their number is always restricted. The insertions on the ventricle are always more distinct than those on the cæcum; the latter being rarely isolated, but usually uniting into a smaller number of common branches, and sometimes into one.

Metamorphoses.

The *salivary vessels* consist of floating tubes, which open about the pharynx, and furnish a liquid to assist in deglutition. They are sometimes wanting or imperceptible, and are more general, as well as more highly developed, among the suctorial than the masticating tribes. The receptacles which supply the silk used by spinning caterpillars, are by many regarded as analogous to salivary glands, as are likewise the organs which furnish the venomous fluid in the mouths of Scolopendræ.[1]

CHAPTER IV.

THE METAMORPHOSES OF INSECTS.

As frequent reference is made, in the course of this treatise, to the metamorphoses of insects, we shall here endeavour to explain in what these essentially consist. "Were a naturalist," observe Messrs Kirby and Spence, "to announce to the world the discovery of an animal, which for the first five years of its life existed in the form of a serpent; which then penetrating into the earth, and weaving a shroud of pure silk of the finest texture, contracted itself within this covering into a body without external mouth or limbs, and resembling more than any thing else an Egyptian mummy; and which, lastly, after remaining in this state without food and without motion for three years longer, should at the end of that period burst its silken casements, struggle through its earthy covering, and start into day a winged bird,—what think you would be the sensation excited by this strange piece of intelligence?" Yet the difference which exists between the sometimes repulsive aspect of a creeping caterpillar, and the consummate beauty of the gorgeous butterfly to which it gives existence, is as remarkable as any supposable change from one form of animal life to another.

Although the ancients appear to have been aware that many insects, such as butterflies, bees, and beetles, proceeded from eggs, and underwent those changes which we name metamorphosis; yet, very shortly before the time of Redi, Swammerdam, Malpighi, and Leeuwenhoeck, to whom we owe so much of our present knowledge, Mouffet, who has been called the father of entomology, mistook the aquatic larvæ of Libellulæ for creatures entirely distinct from the perfect insects, and named them *Water Locusts!* The error was excusable, and has no doubt often been repeated in corresponding cases; for how many are ignorant, even at the present day, that the slender red-coloured wriggling worm, which is so often seen in collections of rain water,

---

[1] Whoever inclines to enter fully into these subjects, will find in Messrs Kirby and Spence's *Introduction to Entomology*, not only a very ample and able account of the structure and functions of the various organs of insects, but also such references to the best informed writers, as will unfold a wide field for further study and reflection. See also *Entomologia Edinensis* (Introduction); the article *Insectes* in the *Dict. Classique d'Histoire Naturelle*, t. viii.; and M. Dufour's papers on Insect Anatomy, in the *Annales des Sciences Nat.*

Metamorphoses.

is the larva state of a clear-winged and elegantly formed fly, furnished with feathered antennæ and long slender limbs, the *Chironomus plumosus*? How entirely dissimilar is the hairy caterpillar, which we frequently observe crossing our foot-path in country lanes, from the richly attired tiger-moth which it eventually becomes? Many examples of a similar nature will probably occur even to the least instructed reader.

The word metamorphosis seems to have passed originally from a mythological meaning to a term in natural science. We had deemed it an ancient phrase, till we were informed by Mr Kirby that μεταμορφοω, and its derivative μεταμορφωσις, are not extant in any Greek writer before the date of the New Testament. They are used to express any *external* change of form or colour, and metaphorically any *inward* change and progressive improvement of the mind. The word metamorphosis, as applied to insects, is in fact synonymous with the more familiar term *transformation*, although, speaking strictly in relation to physiology, the changes indicated by these expressions should rather be regarded as a series of developments.

All insects proceed from eggs either previously deposited by the female parent, or, as in the case of the so-called viviporous (strictly ovo-viviporous) kinds, hatched within the body of the mother. Their first active condition is that of larva, which, according to the views of Swammerdam, contains within itself the germ of the future perfect insect, and those various envelopes, each of which, successively developed, becomes external and apparent by the casting off of that by which it was preceded.

Thus a caterpillar may be viewed, not as a simple, but a compound creature, containing within it the germ of the future butterfly, inclosed in what will become the case of the pupa, which is itself included in several more envelopes or skins, each of which becomes external in its turn. As the larva (so called from the very circumstance of its containing the *imago*, or perfect insect, shut up as it were in a *mask*) increases in dimensions, the various parts expand, and are thrown off, until at length the completed and more beautiful form is displayed in all its lustre. Swammerdam, in fact, discovered, by careful dissection, not only the skins of the larva and pupa incased within each other, but within these again the very butterfly itself, with its organs all complete, though nearly in a fluid state.[1]

Of the same fact, Mr Kirby states, any one may convince himself, without the skill of the great Dutch observer, merely by plunging into vinegar or spirit of wine a caterpillar about to assume the pupa state, and allowing it to remain there for a few days till it gains consistency of parts; or by boiling it for a few minutes in water. A very rough dissection will then enable the student to detect the future butterfly,—the wings being rolled up into a sort of cord, and lodged between the first and second segments, the antennæ and trunk coiled up in front of the head, and the legs, though very dissimilar in form, actually sheathed in those of the caterpillar. Malpighi, moreover, discovered the eggs of the future moth in the chrysalis of a silk-worm only a few days old;[2] and Réaumur those of *Bombyx dispar*, even in the caterpillar, seven or eight days prior to its change into the pupa state.[3]

According, however, to the more recent doctrines promulgated by Dr Herold, the successive skins of the caterpillar, the case of the pupa, and the members of the perfect insect (except the sexual distinctions, which he perceived even in the newly excluded larvæ), do not pre-exist as germs, but are formed successively from the *rete mucosum*, which itself is formed anew upon every change of skin, from what he denominates the blood, or the chyle after it has passed through the pores of the intestinal canal into the general cavity of the body, where being oxygenated by the air-vessels, it performs the nutritive functions of blood.[4] These proceedings, as usual, are attributed to a *vis formatrix*, a term of most convenient application where the mysterious workings of nature are but dimly seen or vaguely understood. But whatever may be the mode or principle of development, we know that insects exist in the four following states,—the *egg*, the *larva*, the *pupa*, and the *imago* or perfect condition.

The first stage of *life*, properly so called, is that of larva, in which existence is usually more prolonged than in any other, and in which the insect does nothing but eat voraciously, and increase rapidly, with intervals of repose occasioned by repletion. In this state it is entirely sterile. In the course, and towards the termination, of the larva state, that peculiar internal secretion the caul, epiploon, or fatty matter, formerly mentioned, is observed to increase, and the insect then assumes the pupa state, which is usually one of inaction and apparent torpidity. Ere long the skin of the pupa bursts asunder, or the wings and members become sufficiently developed for active exercise, and the insect assumes the perfect state, as exemplified in bees, beetles, and butterflies, all of which proceed from a worm-like larva. In this condition they are usually less voracious, their principal object and occupation being the preservation or continuance of their kind.

All insects, however, do not pass through these transformations. Most of the apterous kinds issue from the egg in a form very similar to that which they maintain throughout their after lives; from which circumstance Linnæus and others have bestowed the name of *complete pupæ* on their intermediate state, when such is recognisable. Even those that are subjected to the signal changes above described, differ considerably in the nature and degree of metamorphosis to which they are subjected. Many of the winged kinds experience no other change than the accession of the organs of flight. Their larvæ resemble the perfect insect, with the exception of the want of wings. Their pupæ, known as *semi-complete*, merely differ from the larvæ by exhibiting the rudiments of those organs the eventual development of which produces the completion of the perfect insect. Such are the grasshopper and locust tribes, in which the pupæ continue to exercise their locomotive powers and ordinary vital functions. Those insects which undergo a more entire metamorphosis are changed from larvæ into motionless and inert pupæ, and this mode of transformation presents different gradations. The pupæ, or nymphs as they are often called, of the Coleoptera and several other orders, exhibit their external members in close approximation to the body, but *free* or uncovered by any general envelope; we name them *incomplete*. But among the Lepidoptera, such as butterflies and moths, an elastic but firm and sufficiently solid skin or integument is moulded over the entire body and its various members, and only shows the form and outline of the latter visibly impressed upon its surface. These were called *pupæ obtectæ* by Linnæus. Dipterous flies, again, are covered in the pupa state by small simple cases, or egg-like shells, usually regarded as the skin of the larva, through which the form and proportions of the parts are in no way discernible. These were termed *pupæ coarctatæ* by the great Swedish naturalist.

When, however, we make use of the term *metamor-*

---

[3] *Memoires*, i. 359.

[4] *Entwicklungsgeschichte der Schmetterlinge.*

phosis, in relation to the different states of insects, another meaning is apt to result from the application of the words complete, semi-complete, and other adjective phrases,—for the less complete the pupa, the more complete the metamorphosis. Some confusion, we think, has arisen from this circumstance,—at least we have ourselves been occasionally puzzled by the contrariety of opinion expressed upon the subject even by the "master spirits" of entomology. Thus, Latreille observes, "Les Coléoptères subissent une métamorphose complète,"[1] while Mr Kirby has it "Metamorphosis *incomplete*,"[2] and the same form of expression is used by Mr Macleay.[3]

However this may be, our entire range of natural knowledge presents us with nothing comparable in singularity or beauty with the phenomena of metamorphosis. No wonder that the mystical sages of Egypt, and the refined philosophers of Greece, were so entranced or delighted with what they saw and fancied, as to found upon these changes many of the fondest fables which now pervade our classical literature. "Psyche," says Dr Nares, "means in Greek the human soul; and it means also a butterfly, of which apparently strange double sense the undoubted reason is, that a butterfly was a very ancient symbol of the soul. From the prevalence of this symbol, and the consequent coincidence of the names, it happened that the Greek sculptors frequently represented Psyche as subject to Cupid in the shape of a butterfly; and that even when she appears in their works under the human form, we find her decorated with the light and filmy wings of that gay insect."[4] Swammerdam himself, although his observations tended to prove that the analogy between the metamorphosis of a butterfly and the resurrection of the body, or second life of the human soul, was not so close as had been imagined, is yet of opinion that the process is so remarkable as to paint and exemplify that resurrection before our eyes.[5] "To see, indeed, a caterpillar crawling upon the earth, sustained by the most ordinary kinds of food, which, when it has existed a few weeks or months under this humble form, its appointed work being finished, passes into an intermediate state of seeming death, when it is wound up in a kind of shroud and incased in a coffin, and is most commonly buried under the earth (though sometimes its sepulchre is in the water, and at others in various substances in the air); and, after this creature and others of its tribe have remained their destined time in this deathlike state, to behold earth, air, and water, give up their several prisoners; to survey them, when, called by the warmth of the solar beam, they burst from their sepulchres, cast off their cerements, from this state of torpid inactivity come forth as a bride out of her chamber,—to survey them, I say, arrayed in their nuptial glory, prepared to enjoy a new and more exalted condition of life, in which all their powers are developed, and they are arrived at the perfection of their nature; when, no longer confined to the earth, they can traverse the fields of air, their food is the nectar of flowers, and love begins his blissful reign;—who that witnesses this interesting scene can help seeing in it a lively representation of man in his threefold state of existence, and more especially of that happy day, when, at the call of the great sun of righteousness, all that are in their graves shall come forth, the sea shall give up her dead, and death being swallowed up of life, the nations of the blessed shall live and love to the ages of eternity?

"But although the analogy between the different states of insects and those of the body of man is only general, yet it is much more complete with respect to his soul. He first appears in this frail body—a child of earth, a crawling worm, his soul being in a course of training and preparation for a more perfect and glorious existence. When it has finished this course it casts off this vile body, and goes into a hidden state of being in Hades, where it rests from its works, and is prepared for its final consummation. The time for this being arrived, it comes forth clothed with a glorious body, not like its former though germinating from it, for though 'it was sown an animal body, it shall be raised a spiritual body,' endowed with augmented powers, faculties, and privileges, commensurate to its new and happy state. And here the parallel holds perfectly between the insect and the man. The butterfly, the representative of the soul, is prepared in the *larva* for its future state of glory; and if it be not destroyed by the ichneumons and other enemies to which it is exposed, symbolical of the vices that destroy the spiritual life of the soul, it will come to its state of repose in the *pupa*, which is its Hades; and at length, when it assumes the *imago*, break forth with new powers and beauty to its final glory and the reign of love."[6]

Swammerdam, to whom we owe the earliest philosophical examination of the subject, divides the phenomena of metamorphosis into four classes. In the first, in which the changes are the least varied or remarkable, he includes apterous insects commonly so called, most of which we now name Myriapoda, and the metamorphosis of which consists in gaining additional segments and pairs of feet; also Arachnides and Crustacea, which are for the most part characterized by simple renewals of their envelope. In the second class he places such insects as are born with six feet, but have their wings concealed or inclosed in a sheath during a rudimentary period, such as Orthoptera, Hemiptera, and many Neuroptera. In the third class are included those insects which exhibit three distinct conditions; they compose two subdivisions. The first comprises those insects of which the second state, called nymph or semi-nymph, exhibits either the appearance of feet and wings, or the reality of these organs. They are not reduced to that state of utter lethargy or apparent death which some present, and they include the remainder of the Neuroptera, the Hymenoptera, and the Coleoptera. The other subdivision contains the Lepidoptera, of which the larvæ, commonly called caterpillars, are subject to several preparatory changes of their coat, and are finally converted into chrysalids, through the coriaceous skin of which the interior parts are perceptible, but which externally exhibit neither wings nor legs, nor any other members.

[1] *Règne Animal*, t. iv. p. 354.

[2] *Introduction to Entomology*, vol. iv. p. 369.

[3] *Horæ Ent.* p. 440. The confusion above referred to may perhaps have arisen from certain adjective phrases having been at times applied indifferently, either to the state of pupa or the phenomena of transformation, which in most cases causes a contradiction in terms. In Orthoptera, of which the pupa is semi-complete, the metamorphosis may bear the same designation; but in the other orders the double application of any of the adjective terms leads to inaccurate ideas. Thus, in Coleoptera, the pupæ are *semi-complete*; but there is surely a total transformation, that is, a *complete* metamorphosis, when we compare together the larva and the perfect insect. So also in Lepidoptera, the pupa is obtected; in Diptera, coarctate; and consequently the metamorphosis must be *complete* in both. Now Mr Kirby makes use of the phrase "metamorphosis obtected" in regard to the former, and "metamorphosis coarctate" in relation to the latter,—terms which we have been in the practice of applying to the pupa state of these orders, but not to the general transformations. The same admirable author, in defining apterous insects, states the metamorphosis to be *complete*. We would rather say that they undergo *no* metamorphosis at all,—for which very reason, each particular state, or rather period, of the insect, is itself complete from youth to age. The less complete the pupa, the more complete the metamorphosis, and *vice versa*.

[4] *Essays*, i. 101.

[5] Hill's Translation of the *Biblia Naturæ*, i. 187.

[6] *Introduc. to Ent.* vol. i. p. 75.

Finally, in the fourth class are included all those insects which on their exclusion from the egg exist as vermiform apodal larvæ, are provided at most with six feet, and are converted into nymphs without a change of envelope, so that their skin merely hardens over the intermediate state of the insect, which ere long issues winged. Such are the dipterous tribes.

These views and combinations have been somewhat modified in later years, by Réaumur, Linnæus, Fabricius, Huber, Dutrochet, Savigny, Marcel de Serres, Latreille, and others who have devoted themselves to the investigation of metamorphoses. Those phenomena have consequently been classed as incomplete or partial by which the aspect of the insect is merely modified, and as complete or total by which it is entirely changed. In all, the interior changes may be said to command the exterior, that is, the latter are consequent on the former. In numerous species, not less than three of the principal organic systems, viz. the *nervous*, the *nutritive*, and the *respiratory*, undergo important modifications, and we may easily conceive how strongly the instinctive habits of the individual must be thereby affected. The alterations in the nervous system especially, are singular in their nature and effects. The number of ganglia of the spinal cord is usually greater in the larva than the perfect insect, although the great single ganglion of the rhinoceros-beetle (*Oryctes nasicornis*), in its early state, compared with the four ganglia of its subsequent condition, offers an exception to the general rule. But in the larva of the stag-beetle (*Lucanus cervus*) we observe eight ganglia, besides a recurrent nerve, while the perfect insect possesses only four; and among caterpillars in general the same restriction takes place in the number of their ganglionic knots as they attain the perfect state.

Among beings in which the parts representing the brain and other organs of sensation of the higher tribes undergo so many variations even in the same individual, we may well suppose that whatever ideas they are capable of conceiving at one period of their existence, may differ essentially from those with which they are impressed at another. We shall not here involve ourselves in the discussion of the difficult and dissimilar theories of instinct, nor enter into any exposition of the mechanical, the intellectual, or the supernatural character of that surprising manifestation, which, under whatever aspect it may be viewed, whether as differing in kind or only in degree from reason, cannot be otherwise regarded than as a most beautiful illustration of divine benevolence. But we may ask, by what peculiar memory or mode of recollection does the brilliant butterfly, which seeks its sustenance in the nectarous juices of flowers, rifling their sweets with its tubular *proboscis*,—by what means does it remember that its progeny, while in the larva state, must be sustained by a far different diet, and that they exercise their *jaws* on cabbage-leaves, and other vegetation of the coarser kind? M. Virey, who denies all intellect to insects, and views their various actions as resulting mechanically from the peculiar disposition or character of their nervous system, has endeavoured to illustrate the subject by the following parallel. He compares an insect to one of those portable organs, of which the cylinder has different airs noted on its surface, and which performs one or another tune in proportion as the cylinder is made to recede or advance. So likewise the nervous system, or series of ganglia along the double medullary cord, of the creatures now under consideration, being differently constituted in the larva and the perfect insect, ought to produce different actions in the two cases, though respectively appropriate to the nature of each. Art in the one instance, and nature in the other, has impressed certain dispositions, or notes of action, fixed in a determinate series, equally in the musical organ, and the ganglionic system of caterpillars. Hence the one gives utterance to a certain air, while the other acts according to a certain sequence of operations. Pull out a notch of the barrel organ, and you have another tune; await the transformation of the caterpillar to a butterfly, and you have (with a change in the *notching* of its nervous system) another series of instinctive operations. In both, the relations of cause and effect are the same, and each is merely the mechanical playing of an instrument![1] Now, to prove this position, as has been elsewhere remarked, M. Virey ought at least to have shown, that whenever a change takes place in the instincts of insects in their different states of larva and imago, a corresponding change also takes place in the structure of the nervous cord.[2] But this is by no means the case. In three entire orders, namely, Orthoptera, Hemiptera, and Neuroptera, the structure of that cord remains unchanged, and yet we know that thousands of the species which compose these orders acquire instinctive habits in their perfect state, altogether dissimilar to those by which they were characterized in their earlier condition. Even were it otherwise, our query would still require to be answered, by what mechanical impulsion is the completed butterfly, a gay and gorgeous honey-sucker, induced to play a tune (we speak in harmony with M. Virey's views) so completely in accordance, not with its own refined tastes, but with the future welfare of the crawling caterpillars of which it is the parent? Why does it deposit its eggs, not on the odorous blossoms and bright consummate flowers in which it takes so much delight, and amid the varied petals of which it rejoices to expand to the sunshine its own still more brilliant wings, but on the rank leaves of the cabbage and cauliflower, or the dingy foliage of the nettle? These questions, and many others of a similar nature, are perhaps more easily proponed than answered. When we consider, indeed, how frequently inaccurate is our knowledge even of our own individual feelings, and how much more incompetent we are to judge of what passes in the minds of others of our own species, need we wonder that the sentient principles of the lower animals should, in relation to human intelligence, be still shrouded in dim eclipse, if not in total darkness.. It is far more probable, however, that the alterations in the nervous cord have no necessary connection with the changes of instinct, but are more closely concerned with those other not less remarkable mutations in the organs of sense and motion, which occur between the larva and imago states of several orders. "In a common caterpillar, the form of the body, the legs, the eyes, and other organs of the senses, all strikingly differ from those of the imago; whereas, with the exception of the acquisition of new wings, a perfect locust differs little from its larva; so that we may reasonably expect a corresponding change, such as we find it in the structure of the nervous cord of the lepidopterous insect, not called for in that of the neuropterous (orthopterous?) species, in which accordingly it does not take place."[3]

Metamorphosis frequently induces no less remarkable changes in the *system of nutrition* of insects, followed of course by corresponding alterations in their instinctive appetites and modes of life. In such as undergo an incomplete metamorphosis, the parts of the mouth, and the form of the alimentary canal, experience no essential alteration; but among those tribes in which the change of external aspect is complete in each successive stage, these import-

Metamorphoses.

ant parts assume another character, and admirably illustrate the multitude of means employed by nature to vary her innumerable products, even although the general laws by which these are regulated, and from which, under the great and never-slumbering eye of Omnipotence, they more immediately result, are themselves so few in number. The shorter the alimentary canal becomes, the more carnivorous are the tendencies of the individual. This finally exemplifies the great physiological truth previously deduced from the difference between the structure of the alimentary system in herbivorous and carnivorous animals of the higher classes,—between the short canal of the blood-thirsty tiger, and the lengthened convolutions of the gentler ruminating tribes. Here, however, the disparity exists, not as among animals of entirely different attributes, but in the same individual at different periods of its existence. The young of many aquatic beetles of the family of *Helophoridæ* are carnivorous in their larva state, and become herbivorous on assuming their final transformation. A like singularity is manifested by many dipterous flies, which, born and bred amid the putrid moisture of animal remains, no sooner become winged insects, than they seek a purer diet in the nectarous juices of fruits and flowers.[1] Analogous changes take place even in those species which do not entirely alter the nature of their diet. A voracious caterpillar, which, by means of its robust maxillæ, rapidly gnaws and consumes a quantity of the most coriaceous leaves, to the amount sometimes of triple its own weight in a single day, and presents the beau-ideal of an eating machine, has its intestine greatly dilated, and pursed like a colon. The larvæ both of wasps and bees have a stomach so vast, that it occupies almost the entire of their interior, although in the perfect state of each it becomes greatly restricted. Thus in the bee that great laboratory consists of little more than two unequal honey pouches; and among butterflies, of which the trunk or sucker corresponds to the previous jaws, the stomach is much less than in caterpillars. This, we may observe, reverses the rule which applies to the great ruminating animals among the vertebrated tribes, where we find a single stomach in the fœtus state, and which in the adult is multiplied to four. It is the opinion of some naturalists that larvæ in general, having larger intestines, tend more towards a herbivorous diet than perfect insects, in which these organs are shorter, and which are consequently supposed to assume a more carnivorous habit;—"so rare is it," observes M. Bory St Vincent, "to perceive the manners of living creatures not tending to mutual destruction as their powers are developed." An enlightened mind, however, naturally delights in the perception and extrication of general rules; and these, we fear, are not seldom fancied without being either perceived or deduced. In opposition to the presumed law, we have already mentioned the *Helophoridæ*, which reverse the rule; and to these we could add many more. The glow-worm in its larva state is greedy of animal juices, and feeds chiefly on minute testacea, while, in its completed state, it is entirely herbivorous. A large aquatic beetle, the *Hydrous piceus*, is so ferocious and blood-thirsty in the form of larva, as to bear in France the name of *ver-assassin;* but in its after condition, through the medium of metamorphosis, the intestine becomes elongated, and the disposition of the insect is softened and subdued, so that it then prefers a vegetable to an animal diet. In fact the great aim and object of an insect in the perfect condition is rather the continuance of its kind than the sustenance of itself; although, as the one process cannot be well accomplished without the other, it no doubt, even in its most high and palmy state, casts, like its betters, an occasional eye on the "flesh-pots of Egypt."

The changes in the *respiratory system* of insects produced by metamorphosis, are not less extraordinary than those to which we have just alluded. But as we have already mentioned some of the more remarkable of these in our observations on the *organs of respiration*, we shall not further dilate upon that portion of the subject.

Metamorphosis in insects has been described as the maximum state of a general law of nature, by which the whole organization of the animal being is gradually developed and made fit for reproduction. Without the study of this phenomenon, we cannot acquire a knowledge of the most important circumstances in the lives of such animals as are guided entirely by instinct; and just as an acquaintance with the whole life of an insect necessarily induces a truer knowledge of its actual nature, than a mere description of one of its forms,—so, in the same proportion, it has been said, ought metamorphosis to outweigh every other principle of arrangement. When we trace the natural history of a dragon-fly (*Libellula*) from the time that the egg is first dropped into the bosom of the uncertain waters, till, on some bright sunny morning in "the leafy month of June," the gauzy-winged insect in the perfect state is seen to rise from its moist abode, and, hawking for flies, to hover like a bird of prey along the placid shores of some familiar pool, we can scarcely conceive a clear idea of the truth, except by supposing one animal to have been so inclosed within another, that the imago is in a great measure distinct from the repulsive larva, and is only opened to our view by its desiccation or death. Hence, as Mr Macleay observes, a system unconnected with metamorphosis may be regarded as taking no more notice of half the number of true insects than if they did not exist. "It is the defect both of the artificial system in Entomology, and of the sexual system in Botany, that they become useless, except when the objects of the respective sciences are before us in one particular state, which is often the most transitory of their life. Unless this condition be fulfilled, such systems lose their sole and peculiar merit of being dictionaries by which natural objects may be named. There are thousands of organized beings, to the history and knowledge of which the disciple of Linnæus and Fabricius has no clue whatever, although perhaps they are in that state of their existence which most directly affects the interests of man. Plants not in flower, and insects not in their declared state, constitute an ocean of difficulties, in which the most skilled in the Linnæan nomenclature will founder, unless he have other beacons than such momentary considerations as are afforded by the number of stamina, or the form of the antennæ."[2]

We shall conclude our observations on the singular subject of metamorphosis, by another quotation from the last-named author, which, with what has been already stated, will, it is hoped, suffice to instruct the reader regarding what we consider the most extraordinary phenomena observable within the range of the animal kingdom. "It was perfectly in unison with the innate propensity of the human mind towards the marvellous, that the change of a caterpillar into a butterfly, when first noticed, should have been considered by the ancients as a true transformation, irreconcilable with the ordinary course of nature. Even on the mystery being in a great degree cleared up by the discoveries of Libavius, Redi, Malpighi, and Swammerdam, the phenomenon continued to be termed metamorphosis; and perhaps it is even still a little owing to such circumstances that a natural process, neglected in other branches of zoology, has always excited so much curiosity among entomologists. Metamorphosis, however, has been taken of late in a very general point of view, and rendered synonymous with that species of organic decomposition which, by means of continual shedding of the external envelopes, or even of the various integuments which may compose those envelopes, occasions that extraordinary characteristic of a living body, namely, that it never remains in a constant state, or identically the same, but is continually assimilating new particles of matter, as it throws off the old. And since no metamorphosis can take place except in consequence of these integuments being shed, perhaps it may not be altogether improper to survey the subject in this light. What I mean is, that we ought to regard the metamorphosis or change of form which certain animals undergo at various periods of their life, as an attendant upon, if not a variety of, the *ecdysis*, or moulting, to which all organized beings are subject. There is, however, a great distinction to be made between the *ecdysis* of the *Vertebrata* and *Annulosa*, for in the former we observe little more than that the animal has quitted a sheath in which it was inclosed; whereas in the latter the change is nothing else than if the skeleton were shed; for this name is surely deserved by those hard and solid parts which in so many cases afford support to the muscles. It is clear that such a process must occasion a crisis in the life of an annulose animal, incomparably more decisive in its effects than what can be produced among the *Vertebrata*, by merely being set free from an integument. All the marvellous, however, of *ecdysis*, was with the earlier naturalists comprehended in the change of form; and consequently the shedding of the envelope only excited attention where it regarded a few of the *Annulosa*. Hence it was a great discovery of Linnæus, that every annulose animal ought to be considered as subject to metamorphosis. It may indeed have led to his more artificial notion of every externally articulated being having a nympha state; but even this helped Fabricius to give, although with a faulty nomenclature, a much more convenient division of metamorphosis than he could otherwise have devised.

---

[1] *Entomologia Edinensis*, p. 207.

[2] *Hor. Ent.* p. 449.

"Ecdysis, by which term is signified generally every change in the identity of the envelope of a living body, may either be complete or incomplete. If it be incomplete, or, which is the same, if the integuments scale off piece by piece, we have that mode of change which is peculiar to the most perfect of the *Vertebrata*, and to the least perfect of the *Annulosa*.

"Complete ecdysis is the shedding of the whole external envelope at once, of which we have examples among the vertebrated as well as annulose animals. It is of three sorts; first, where the external envelope is shed without producing any essential change of form, except in as much as may relate to the increased size. In those larvæ of insects which become inactive in their pupa state, such a process may always be distinguished from the true metamorphosis; but in apterous Hexapods having active nymphæ, they are necessarily confounded. It is also visible in reptiles and spiders, where such appendages of the trunk as have been lost may be reproduced by continued moulting. When the various envelopes are all cast as it were in one mould, it is to be expected that the proper form of the animal should re-appear as these continue to be thrown off. The return therefore of a spider or crab, after having lost a limb, to its original form, may be in some measure understood as depending on the manner in which such animals shed their envelope; but that the limbs thus shot forth should be furnished with muscles and nerves, is, I conceive, what cannot be accounted for, except by referring to that polype nature of the cellular substance, which is perhaps, in the opinion of some persons, the foundation of all ecdysis. If perfect hexapod insects cannot reproduce their members, this inability may probably proceed from a cause which appears to have produced the same effect among *Mammalia* and birds, to wit, that these animals in their perfect and final form are all subject, if to any, at least to a very imperfect ecdysis.

"The second sort of complete ecdysis is that where the under envelope has been cast in a somewhat different mould from the upper, so that in the course of the moulting certain new parts become gradually developed without the general form being in any material degree altered. This is observable in every annulose class, as well as in Humboldt's Axotl among the *Vertebrata*, and is the first species of change which merits the name of metamorphosis. It includes the *Metamorphosis inchoata* and *Metamorphosis dimidiata* of Latreille, and is the same with the *Metamorphose partielle* of Lamarck.

"The third sort of complete ecdysis is that wherein, by some two or three moultings, generally the last which the animal has to undergo, the form is entirely changed, as well as the number of appendages more or less increased. This is clearly a true metamorphosis, and includes the other two sorts of complete ecdysis; for we have here combined a total casting of the integuments, a development of additional appendages, such as feet or wings, and finally an entire change of form. Such a combination may be witnessed, among the *Vertebrata*, in frogs, and, among the *Annulosa*, in certain hexapod insects. Hence, in confining ourselves to plain and open ecdysis, there will be no great error in stating that the most imperfect takes place in the highest *Vertebrata* and the lowest *Annulosa;* while the most complete ecdysis is that which is seen to prevail in the highest *Annulosa* and some of the lowest *Vertebrata.*

"In strict accuracy, however, it appears that we ought to acknowledge the existence of complete ecdysis throughout the circle of *Vertebrata.* Nay, some physiologists have attributed insect metamorphosis itself to a shedding of an envelope analogous to that which contains the fœtus of the more perfect *Vertebrata.* As every embryo, whether animal or vegetable, is enclosed in a tunic more or less solid, which is its chorion, so, proceeding with the analogy, they conceive that there must be some condition for every animal, similar to the state of the fœtus of the more perfect animals when surrounded by the amnios; and this state in batrachian reptiles and hexapod insects they hold to be the larva. The only danger of this reasoning is, that while we find the birth of an animal to be attended with complete ecdysis, we may be apt to imagine that every complete ecdysis betokens a true birth. It would, however, be truly absurd to consider the casting of their shell by *Crustacea*, or the periodical moulting of the serpent, in this light; yet no one can doubt the fact of both these being cases of complete ecdysis, only differing from that of *Lepidoptera*, because in the former animals the external envelope is always of the same form as that of which it is to take the place. The truth perhaps is, that we ought only to allow two states to every animal, a perfect and an imperfect state. Then, by the reflection that no animal out of the circle of *Aerita* can ever arrive at its perfect state except by means of metamorphosis, and that when perfect it can never again be subject to this change of form, though it may still moult or shed its external envelope, we may be able, if not to comprehend the cause, at least to know the effect, of some of the most puzzling phenomena in nature. The true criterion of animal as well as vegetable perfection is the ability to continue the species; hence some of the *Vertebrata*, as well as *Annulosa*, gaining this faculty before they have arrived at their proper type of form, metamorphosis ceases, and they preserve the shape of larvæ.

Relative Position in the Animal Kingdom.

"But if a complete ecdysis may sometimes create a total change in the external appearance of the animal, the fact, however astonishing, is nothing in comparison of the internal metamorphosis which accompanies it, and of which as yet no philosopher has been able to give any satisfactory explanation. The generalization indeed by which we have reduced the moulting of a bird's feathers and the metamorphosis of a butterfly to one principle, may appear to be strained beyond its proper limits; yet if we contemplate the regular gradation from one to the other, how truly, for instance, the inactive pupa of a beetle corresponds with the agile nympha of a *Gryllus*, how this ecdysis in an apterous *Gryllus* corresponds with the sloughing of a spider, and this again with the annual renovation of the serpent, we must be sensible that, however dissimilar the extremes may be, all these changes are modifications of one principle. But what particularly deserves remark is, that these extremes should often be visible in neighbouring groups; nay, in the same order; that, in short, metamorphosis should differ so much in degree even where the animals are near in affinity. An orthopterous insect may preserve the same form and habits from the instant it quits the egg up to the period of its death, the only qualities obtained by ecdysis being an augmentation of size and an aptitude to continue the species. But if we turn to the order of *Coleoptera*, which is contiguous in affinity, it is truly wonderful that, by metamorphosis, not only the form, but the nervous and digestive systems, may be altered, and the organs connected with these primary functions may all be of a construction different from that which they originally possessed."[1]

The reader has now been made acquainted in a general way (and as precisely as the limits of our present article may admit) with the most characteristic features in the structure of the insect tribes, from which he may form some opinion of their real nature. Their relative position in the magnificent range of created things is a subject deserving of a deeper and more extended examination than we can here bestow upon it; but as we are unwilling to leave such an interesting matter of philosophical consideration entirely unregarded, we shall here enter into it in the only way compatible with our prescribed limits.

CHAPTER V.

OF THE RELATIVE POSITION OF THE CLASS OF INSECTS IN THE ANIMAL KINGDOM.

A great diversity of opinion has existed from the earliest ages regarding the natural affinities of the different kinds and classes of animated beings to each other, and a consequent contrariety has prevailed in our systems of classification, which are of course indications of the relation of groups, unless where, for mere convenience, a professedly artificial basis of arrangement, deduced from one or two obvious though unimportant characters, may have been adopted. The majority of naturalists, both ancient and modern, have proceeded upon the idea that all natural objects were *concatenated*, or formed a continuous *chain* or linear series, and that whatever hiatus might seem to exist arose either from some great convulsion which had swallowed or swept away the desired links, or from these links being still to be discovered in one or other of those regions of the earth's surface which still remain to be explored. Hence the dictum of Linnæus—natura saltus non facit. "When the ALMIGHTY CREATOR," says Mr Kirby, "willed to bring into existence this mundane system, he formed it according to a preconcerted plan, with all its parts beautifully linked together and mutually corresponding. All things were ordered in *measure*, and *number*, and *weight*.[2] There was nothing deficient, nothing superfluous; but the whole, in the strictest sense, 'was very good,'[3] and calculated in the highest degree to answer the purpose of its GREAT AUTHOR."[4] Observation and analogy alike combine to prove that there is a regular approximation to each other in the works of God, and that they are related to each other in a variety of ways both naturally and analogically; but it need not be supposed that, in the magnificent plan of the creation, there is no disparity in the relative position of the most nearly related kinds, and no greater interval in one place than another. There is in truth a great variation in the combinations of living beings, though no violent break or sudden interval; in other words, "some continuous species or groups have more characters in common than others." But in considering the various groups of living creatures, we must ever bear in mind our own ignorance of their actual amount, and the thousands of unknown forms which in all the pride of life may be daily unfolding their exquisite forms and gorgeous colours amid those far deserts where man has never trod, and which for that very reason he regards as *solitudes*, though assuredly teeming with all the inexplicable wonders of creation. Let not therefore a *hiatus* be confounded with a *saltus*, the former being merely one of the many blanks in the superficial map of knowledge drawn by man, the latter an absent link in that resplendent chain, to us too often "dark with excessive light," which in one way or other connects together in divinest harmony the beautiful works of the Creator. That the series of beings, however, was not only continuous, but *undeviating*, and ascended in a direct line from the lowest to the highest, was maintained, among many others, by the excellent and ingenious Bonnet, and has generally prevailed till very recent times.

Now the principle which mainly characterizes the views so mildly advocated by Mr Macleay, and entertained, we believe, about the same period, although without communication, by Agardh, Fries, and other continental naturalists, is this,—that although the natural arrangement of objects is indeed in a continuous series, that series in its progression forms various convolutions, each of which may be represented by a *circle* or series returning into itself. He maintains that absolute divisions do not exist in nature, and that a single plan pervades the universe, a plan founded on the principle of series of affinities returning into themselves, and forming circles; hence there is no such thing among natural objects as a simple progression of species.[5]

If it were true that the descending scale, as so long supposed, in the perfection of organization, was regular from man to the infusorial tribes, then the lowest of one form of life would naturally lead to the highest of the next ensuing, and the most simply organized of the vertebrated classes would connect most nearly with the most complex of the invertebrated kinds. But this, as we shall afterwards see, is not the case.

Although naturalists, if we may judge from their sys-

[2] *Wisdom*, xi. 20.

[3] *Genes.* i. 31.

[4] *Introduc. to Ent.* iv. 356.

[5] The latter sentiment appears to have been also entertained by Latreille in his later years. Writing of certain coleopterous insects, he observes, "Les Dryptes ont aussi des rapports avec les Cychrus, et paraissent lier les Cicindelètes avec la section des Carabiques grandipalpes. Plusieurs sections de cette famille semblent se rattacher, comme autant de rameaux, aux Cicindèles. La plupart des autres familles d'insectes sont dans le même cas, ou forment des troncs ramifiés. *En un mot, des séries continues n'existent pas dans la nature.* (Note to *Règne Animal*, t. iv. p. 373.)

Relative Position in the Animal Kingdom.

tems of classification, are accustomed to consider the insect tribes as inferior in the great range of organization to the molluscous animals which inhabit shells, there can be no doubt that they are superior in many of their vital functions. Their powers of locomotion, whether as winged, aquatic, or terrestrial creatures, are finely developed, and their perceptive faculties are much more acute. The symmetrical perfection of their forms, and the articulation of the limbs, in the insect class, seem also in some measure to connect them with the vertebrated tribes. Indeed, even of the latter, many seem far inferior to insects, not only, as Mr Macleay has observed, in the possession of those faculties by which we are accustomed to estimate the rank of the *Vertebrata* among themselves, but also in the complication of their general structure. These and other considerations afford powerful arguments in favour of the *circular* system; for it appears necessary, first, that certain affinities of the *Mollusca* to the *Vertebrata*, and which are obvious in the *Cephalopoda* or cuttle-fish, should not be disturbed by any intervening division; and, secondly, that the annulose animals themselves, such as insects, Crustacea, and Arachnides, should not be far separated from *Gastrobranchus* and other genera of cyclostomous fishes; above all, that they should not be made subordinate in rank to such simply organized creatures as compose the greatest part of the Mollusca. "Now these conditions will all be fulfilled if the chain of nature be viewed as returning into itself; whereas they will be completely violated if we account it to be a regular line or ladder, commencing with the *Infusoria*, and terminating in man; or indeed if we adopt any opinion that has hitherto been advanced on the subject by naturalists."[1] It seems to have been chiefly owing to the perfection of the circulating system in molluscous animals that they have obtained their present rank; for, in regard to the nervous system, which would have been a truer test, although such tribes as possess a distinct head, and are furnished with tentacula and other organs of sense, have undoubtedly a true brain, yet oysters and many more *acephalous* kinds can lay no other claim to the possession of that organ than what is derived from the analogy which its position in these Testacea is supposed to bear to that of the brain in the gasteropoda. It is a strong fact, however, that so skilful an interpreter of nature as Baron Cuvier should have been determined by that analogy, and should have acceded to the acephalous Mollusca the possession of a brain, and a general construction, which, upon the whole, he regards as making a nearer approach to that of the *Vertebrata* than is effected by any annulose animal. Yet in spite of this it would be difficult to contend that an *Ascidia* is in any respect superior to a bee, as no one who has ever seen the two, and observed their respective functions, would venture to bring the sluggish mollusc into competition, either as respects intelligence or complication of mechanism, with the delightful emblem of industry.

When we call in the aid of anatomy to determine the relative importance which different material beings bear in the scale of the creation, we must consider the beauty of the general mechanism and (speaking humanly) the difficulty of the workmanship, and not any "fancied and often forced resemblance to the human structure."[2] It is in truth a great error to regard the works of the creation as referable to the human structure, as a standard of perfection; for although the frame of man, when taken as a whole, ought doubtless to be regarded with wonder and admiration as a most complicated yet complete machine, there is at the same time as little doubt that we scarcely possess a single sense or bodily power in which we are not excelled by some irrational beings. Different animals have in fact been constructed on different plans, and man may without impropriety be regarded as upon the whole the most admirably constructed creature of all those which have been organized upon the same general plan with himself, but with the others he cannot be compared.

In the article ANIMAL KINGDOM of this work we have already shown the importance of the nervous system in the formation of the greater divisions of living creatures, and we there exhibited the relative positions occupied by the different classes of animals in the works of the most distinguished systematic writers. Lamarck divides the animal kingdom into two great branches,—the one containing all those living beings of which the skeleton is *internal*, and constructed upon a bony and articulated column, hence called *Vertebrata*,—the other consisting of those innumerous kinds of which the skeleton is either wanting, or its supposed analogue is for the most part *external*, and includes the muscles; these are the *Invertebrata*. This grand distinction is strongly marked throughout the great mass of each division, but it begins to disappear wherever the provinces approach each other. Thus among the turtles or chelonian reptiles, the vertebral column is converted to a row of square osseous plates, which run along the back, and unite with eight pair of expanded ribs, which are anchylosed together by real sutures, and combine to form in fact the *external* carapace or shell. In like manner the vertebral column almost disappears among the cyclostomous fishes, while, on the other hand, the Cephalopoda, or cuttle-fish, though belonging to the invertebrate division, exhibit the commencement of an internal skeleton. M. Virey, as we have shown in the article above referred to, divided the animal kingdom into *three* great branches, according to the different character of their nervous system. Baron Cuvier, proceeding upon the consideration of the same important basis, includes all animals within *four* primary divisions; while Mr Macleay, according to his peculiar views, perceiving *five* great sub-kingdoms in the magnificent *circle* of living things, has assumed that number of divisions. We shall here present a sketch of his system, so far as relates to the primary forms, the majority of which agree with those of his predecessors, although their relative position, and circular sequence, if we may so call it, differ.[3]

1*st*, There is a great tribe of beings which possess one principal centre to their nervous system, the great trunk of which, with the said centre, is contained in a bony articulated case, which forms the axis of the whole body, and constitutes the vertebræ and skull of these creatures, which are therefore named VERTEBRATA.

2*d*, In another form of animals the skeleton is as it were external, so as to envelope the whole body, and is divided by transverse folds into a certain number of rings, to the internal surface of which the muscles are always attached. Their nervous system consists of two long strings of medullary matter, passing through the whole of the body, and united to each other, at small distances, into several knots or ganglia. These ganglia may be said to perform for the parts which surround them the function of so many brains, and for a certain period are even sufficient for ner-

[1] *Horæ Entomologicæ*, vol. i. p. 206.

[2] *Ibid.* p. 405.

[3] As the book entitled *Horæ Entomologicæ* has been long out of print (the author has never brought out a second edition, and the first was almost totally consumed by fire), our occasional exposition of its peculiar and prevailing doctrines cannot prove otherwise than interesting to the considerate reader.

Relative Position in the Animal Kingdom.

vous sensibility after the animal has been cut in pieces. All the beings so constructed are named Annulosa.

3*d*, In a third prevailing form there is no articulated skeleton either external or internal, the muscles being attached solely to the skin, which is itself in general soft, though often protected by a calcareous or stony crust, termed the shell. These animals, remarkable, like plants, for the variety of modes in which the sexes are combined, have their nervous system composed of several masses or ganglions united together by nervous threads. The constituents of this group are almost all aquatic, and are named Mollusca.

4*th*, A fourth form of animal life exhibits to our view the organs of locomotion and sensation arranged in a circular disposition round a centre, so as to give a sort of radiated aspect to the whole body. They are composed of a more or less gelatinous substance, of which the fibres are indistinct. The nervous system of these imperfect beings is but little known. M. Tiedemann, in a work crowned by the French Institute (*Mémoire sur l'Anatomie des Astéries*), conceives that the whitish threads which proceed in a radiant direction from around the mouth, and which extend themselves through the entire length of the arms of these animals, form a kind of nervous system, which, from the pulpy nature of the medullary matter, seems to correspond with the gelatinous composition of the animals themselves. They are all aquatic, and are named Radiata.

5*th*, Thus far these groups agree in number and constitution with the four primary divisions established by Baron Cuvier,—the *Annulose* division corresponding with the *Animalia Articulata* of the French naturalist, except that it excludes the *Annelides*, or red-blooded worms, and includes certain radiated species (commonly so called), such as the intestinal group denominated *Intestinaux Cavitaires* by the French, or *Entozoa Nematoidea* of Rudolphi. But, according to Mr Macleay's views, there still remains a *fifth* form of animal life to be considered,—a group of beings which cannot in the present state of knowledge be better described than as masses of a transparent, homogeneous, mobile, and sensible pulp. There may, however, be observed in this translucent mass innumerable minute granulations, which may be regarded as the nervous molecules dispersed over, or as it were confounded with, the substance of these animals, so as to endow the whole with sensibility, or something which the author calls such, probably for want of a better name. This final division is named Acrita.[1] Its constituents form a portion of the *Animalia Radiata*, or fourth primary division of the Cuvierian system, and include the infusory animals, many of the intestinal worms, and the *polypi*. Their distinctive character is principally negative in reference to animals, and positive in regard to plants. The simple texture of their cellular tissue is common to them and to the *Algæ*. Their gemmiparous generation is allied only to the very simplest mode of the reproductive system among other animal tribes, but is by no means unfrequent among plants. The method by which they are more or less sustained by the absorption of their external pores, and the attractive influence exercised on them by light, are likewise features only elsewhere to be observed among the vegetable tribes. When a polype is cut in pieces, each of these continues to live, and in time assumes the original form, so that every point of such an animal body may be regarded as possessing an independent life, like that of the lower plants. Lamarck accounts for this peculiarity by regarding their alimentary canal as constituting a second absorbing surface, in no way different from the absorbent external surface of the *Agastria*, or infusorial tribes, so that any portion separated from their bodies may live for a time, like the Infusoria, until they have obtained the second or internal absorbent surface.

"On considering," says Mr Macleay, "the gelatinous composition of these animals, the dispersion of the nervous molecules through their substance, and the absolute certainty that they are devoid of every sense, except perhaps those of taste and touch, we are led to connect them with the *Mollusca*, whose substance is always mucous, and often even gelatinous,—whose nervous system, though collected into several *ganglions*, or *centres of sensibility*, has nevertheless these ganglions dispersed, with little if any arrangement, throughout the whole mass of their body,—and whose senses, so far at least as we are certain of their existence, seem to be confined to those of taste and touch, with the exception of a few animals of the division which possess the organs of sight, and still fewer which possess those of hearing.

"Nevertheless, on comparing the *Acrita* with the *Mollusca*, we find that the organization of these last has become much more complicated, and that a distinct system of circulation, and peculiar organs for respiration, digestion, and secretion, are even visible in these animals, which connect them in a remarkable manner with a still more perfectly organized family—the *Vertebrata*.

"These, however, by their red blood, their muscular heart, their jaws acting vertically, their distinct organs for sight, hearing, smell, and taste, their sexes constantly distinct, their vertebral column, and extreme concentration of the nervous system, are sufficiently insulated from the *Mollusca*, as well as from all other material beings. The group is therefore perfectly distinct and natural; yet if we attempt to define it by any of the above-mentioned various properties, little examination is requisite to convince us that the characteristic thus chosen either disappears in the least perfect of the *Vertebrata*, or passes imperceptibly into the neighbouring groups.

"Thus in the fishes which compose the genera *Ammocætus*, Dum. and *Gastrobranchus*, Bl. all those parts which ought to have constituted their skeleton as vertebrated animals become so soft and membranaceous that they may be considered as having no bones. The organs of respiration and of manducation, the absolute want of the sense of sight, the general habits and external form of these singular fishes, all prove to us that they are connected with the *Annelides*, and that by them nature passes to the structure of the *Annulosa*. On the other hand, on examining some of the *Echinoderma* of Cuvier, such as those composing the genus *Comatula*, we may trace the articulated texture of the *Annulosa* into the division of *Radiata*, many of whose external forms are also exactly imitated by the sessile *Cirrhipedes*. Of the *Radiata*, again, the stellate form and the gelatinous semi-transparent substance are observable among the *Acrita*. So that the chain whose links we have endeavoured to unfold returns into itself, and we find that all animals form a circle composed of the following great divisions, viz.

Acrita,
Mollusca,
Vertebrata,
Annulosa,
Radiata.

---

[1] "Animalia gelatinosa polymorpha, interaneis nullis medullâque indistinctâ. Os interdùm indistinctum, sed nutritio absorptione externâ vel internâ semper sistit. Anus nullus. Reproductio fissipara vel gemmipara, gemmis modo externis modo internis, interdum acervatis. Pleraque ex individuis pluribus semper cohærentibus animalia composita sistunt." (*Hor. Ent.* p. 224.)

Relative Position in the Animal Kingdom.

"This arrangement of animals is, it is true, quite distinct from that generally adopted; but it will be seen that it is not only conformable to nature, but that it removes many of the discrepancies which shock the naturalist in the common systems. For instance, there is an acephalous animal of the division *Mollusca* (*Ascidia mammillaris*, Linn.) which exists without any visible organs of sense except that of taste, whose substance is little better than a homogeneous gelatinous pulp, whose inert nature seems to deprive it of any power like that of voluntary motion; a being which is consequently reduced to fix itself to solid bodies, or to be the sport of winds and waves, whose principal sign of life consists in the absorption and spouting forth of water, and whose animal properties, in short, are all comprised in its irritability, its circulation, and respiration. Yet because these two last qualities appear in this animal, whose existence is little better than vegetative, to bear some resemblance to the circulation and respiration in some of the *Vertebrata*, we find it placed in the common systems before the bee, which astonishes us by its industry and social qualities; before the ant, which excites our admiration by its frugality and courage; and before the other numberless insects, which by their manners and stratagems have often made the naturalist hesitate as to the point where he would draw the line, and separate instinct from reason."[1]

Mr Kirby seems equally inclined to accord a step of precedence to the insect and other annulose or articulated tribes over the Mollusca, or at least to maintain that the latter should not be interposed between the former and the vertebrated tribes. "If you inquire," says he, "into the rank of each of these sub-kingdoms, of course you will assign the principal station to the *Vertebrates*, which are the most perfectly organized, to which man belongs, and over which he immediately presides. If we form the scale according to the nervous system of each province, that in which the organ of sensation and intellect is most concentrated will stand first; and in proportion as this organ is multiplied and dispersed, will be the station of the rest, which will place them in the order in which I have mentioned them; and the *Annulosa*, to which insects belong, will precede the *Mollusca*, which Cuvier and Lamarck had placed before them on account of their system of circulation. But when we reflect that a *heart* and *circulation* occur in some of the conglomerate *Polypi*,[2] animals that approach the *vegetable* kingdom; that some of the acephalous *Mollusca* have no visible organs of sense except that of taste, whose substance is little better than a homogeneous gelatinous pulp, and who seem from their inert nature to have very slight powers of voluntary motion;[3] we shall be convinced that a heart and circulation alone, unaccompanied by a more concentrated nervous system and more perfect structure, cannot place an animal above those which in every other respect so obviously excel them. With regard to *insects* particularly, we may further ask—who that considers how man employs his powers and organs even in his most degraded state, or that contemplates the wonderful works that he is enabled to accomplish when his faculties receive their due cultivation and direction, can avoid regarding him as superior to the rest of the animal creation? And what unsophisticated mind, not entangled in the trammels of system, when it surveys the industry, the various proceedings, and almost miraculous works that have been laid before you,—the waxen palaces of the bee,—the paper cottages of the wasp and hornet,—the crowded metropolis of the white ants,—the arts, the manufactures, and stratagems of other insects,—the associations and labours for the common good of those that are gregarious;—will not at once conclude that they must be a superior race to the slug, the snail, and others, which live only to eat and propagate their kind? Or who, that considers the wonderful structure of the animals whose cause I advocate,—the analogy that exists between their organs of manducation, of motion, and of sensation, and between various other parts of it, with those of the higher animals,—the acuteness of their senses, their wonderful strength of muscle, and powers of locomotion,—but will think them superior to the headless and almost inanimate oyster or muscle, or the conglomerate *Alcyonia*, though they have a heart and circulation. Who, again, that observes, that in proportion as pedate animals approach to the human type, their motions are accomplished by fewer organs,—that man walks, *ore sublimi*, upon *two legs;* the majority of quadrupeds upon *four;* insects upon *six;* the *Arachnida* apparently upon *eight;* most *Crustacea* upon *ten;* and the *Myriapods* and others upon *many*,—but will thence conclude that insects must precede the *Arachnida* and *Crustacea?* Who, once more, that reflects, that if any of the superior animals are deprived of a limb, it can never be reproduced, and that in insects the same circumstance occurs; while spiders and *Crustacea*, if they lose a leg, have the power of reproducing it; and the *Mollusca*, if they are decapitated, can gain a new head,—will consent to their being placed after any of these animals?[4] Lastly, who that recollects that the *Mollusca* are hermaphrodites, like most plants, bearing both male and female organs in the same body, but will allow that insects, in which the sexes are separate, as in the Vertebrates, must be more perfect, and of a higher grade?"[5]

Whoever regards the different classes of the animal kingdom with an observant and discriminating eye, will not fail to perceive that the knowledge of any organ in one particular division of nature is insufficient to enable us to judge of its importance; for such are the changes in the organization of animals, that a system of organs which performs the most important functions in the first division, may either not exist in the next, or be found in a secondary condition, and subordinate to some other system which has acquired the preponderance. In truth, the anatomy of the higher classes having been first profoundly, or at least laboriously studied, before the requisite attention had been bestowed on the structure of Invertebrates, all those organs and functional actions which were invariably more or less sustained and apparent in these first divisions, have been regarded as fundamental, and for this reason alone an equal importance in our systems of classification has been attributed to them throughout the whole animal kingdom. From this course of proceeding, as noticed by M. Straus, approximations have resulted which break the natural relationship of many divisions. For example, in the first great division of animals, respiration and circulation being in fact two functions to which all the rest are more or less subordinate, it has been imagined that we ought to regard them as essential in the whole series of animals, and employ them as the sole basis of classification. Among the Vertebrata these functions indeed afford the firmest foundation for a natural distribution; but amongst other classes, on the contrary, in which they are only secondary, their adoption has led to the

Relative Position in the Animal Kingdom.

gravest errors and most palpable contradictions; for it not unfrequently happens that one family of Invertebrata which respires by branchiæ, cannot be separated (keeping numerous natural affinities in view) from another family in which the respiration is pulmonary or tracheal.[1] One great principle of creation being to combine variety in the means with uniformity in the effect, we find that among molluscous animals the circulation of the blood varies in its manner *ad infinitum*, and has thus led to the most artificial arrangements. Yet few animals in existence have the organs of circulation more complicated than some of the Cephalopoda. Among the annulose animals, also, in which the nature of the nervous system is so uniformly accordant, circulation varies from an extremely perfect to an evanescent state. A mode of nutrition and respiration takes place so entirely different from that exhibited by the vertebrated and molluscous tribes, that they never can be regarded as modifications of the same system. As, then, the general plan of construction of these animals is so different, Mr Macleay regards it as necessary to suppose that the new and dissimilar system of respiration is that which more peculiarly characterizes the annulose group, or, in the author's words, "is that to which the structure of the animals forming the group tends." And what makes this supposition the more probable is, that the Annelides, or red-blooded worms, which, of all the articulated tribes, are placed by Cuvier the nearest to the vertebrated classes, are nevertheless imperfectly organized, and of as dull perceptions as any of the annulose division. This could hardly be the case were the Annulosa to be considered with propriety as modifications of the vertebrated structure, while, on the other hand, those annulose classes which respire by tracheæ, and coincide in nothing with a vertebrated animal, are, nevertheless, the most active and industrious of their group, although their activity and industry are of a nature entirely different from what is observable among the vertebrated tribes. Now it is difficult, if not impossible, to account for all this, unless we regard every vertebrated creature to have been constructed by the great Creator with reference to one type, and every annulose with reference to another; and as the former is more imperfect in proportion as it approaches the annulose structure, so the latter also becomes more imperfect in proportion as it obtains a distinct system of circulation and other characteristics of the vertebrated tribes. It thus follows that the animals which connect them ought to be extremely imperfect in their organization; and this conclusion is well supported by the sluggish Annelides, in which organs of sense are barely perceptible, and organs of motion by no means so perfect as among the larvæ of insects.[2] M. Straus also maintains the opinion that it is the less perfect species of any one great group which approach most closely to the group which precedes or follows them, and that it hence results, that in any division, the species which offer the most elevated organization may be more perfect than such as are placed at the lower confines of a higher division. He admits that a more natural passage exists from the Vertebrata to the Annulosa, than from the former to the Mollusca; but this connection he considers is by the lowest in the scale of organization of each of these groups. As soon as the Vertebrata reach the most simple form compatible with their mode of organic life, the great Author of nature commences from that point a new group, that named *Annulosa*, by successively introducing a new series of organs altogether different from those he has abandoned, and by considerably modifying those he has retained. The genus *Ammocœtes* (and perhaps also that of *Myxine*) form this point among the Vertebrata, while *Gordius* and *Hirudo* compose the corresponding link among the annulose tribes. On either side these animals find their place at the lowest point of the descending scale, formed by each of these two series; and, compared with each other, the two genera of fishes just named, and the abranchial *Annelides*, present some remarkable resemblances in the few organs which they possess.

The opinion that insects and other annulose animals are more nearly connected with the Vertebrata than are the Mollusca, is regarded as true by M. Straus Durckheim, both in regard to the modes of organization according to which these three divisions are formed, and in relation to the degree in which their faculties are developed. The Vertebrata, he observes, are characterized by an articulated body, of which the two lateral halves are symmetrical, and are sustained by an internal skeleton, the central portion of which is composed of a series of parts, to which the other osseous parts are attached. In the Annulosa the symmetry of the two sides of the body is still greater than in the Vertebrata; the body is likewise articulated, and formed by a series of central parts, to which the others are attached, although they have no internal skeleton. The nervous system in both consists principally of a spinal marrow, from which arise most of the nerves of the body; but there is this difference in the Vertebrata,—the spinal marrow is dorsal, whereas it is ventral among the annulose tribes. The muscular system is also as fully developed in the one as in the other, and offers nearly the same distinct forms. The Mollusca, on the contrary, exhibit characters totally at variance with those now mentioned; for, on the one hand, their body no longer exhibits a perfect parity of parts, nor is it in any degree articulated; on the other, the nervous system is not longitudinal, nor its situation constant, while its mass is greatly decreased. The muscular system is also in general much less perfect, and, considered in detail, the muscles are less distinct, and only form, throughout the greater part of the body, a mass of fibres so interlaced as to be incapable of separation, thus conducting us to *Entozoa*, of which the body is only a continuous *parenchyma* without distinct muscles. According to the author last named, the character which eminently distinguishes the Mollusca from the two other divisions is, that in these the organs of *animal*, in the Mollusca those of *vegetable* life, are the most predominant; from whence it follows that the latter are totally devoid of industry, and of that higher mode of perception approaching to *intelligence*, which insects possess in a degree surpassing all other invertebrated tribes.

Having entered into the preceding investigation with the view of illustrating the true position of the annulose division in relation to the other sub-kingdoms of animal life, we shall now, in more direct reference to the proper subjects of our present dissertation, that is, the hexapod or six-footed insects, exhibit, by means of the following diagram, the views entertained by Mr Macleay regarding the natural affinities observable among the annulose tribes themselves. The reader will perceive that the circles of *Mandibulata* and *Haustellata*, with those portions of *Ametabola* named *Thysanura* and *Anaplura*, constitute the true INSECTA, such as we have defined them at the commencement of this article.

Our next subject of consideration is one which has not previously formed a part of any of our encyclopædias of knowledge.

CHAPTER VI.

THE GEOGRAPHICAL DISTRIBUTION OF INSECTS.

This topic has indeed been much less attended to as a matter of philosophical investigation than it deserves. When we take an extended view of the general distribution of animals and plants, we find that they are usually disposed over the earth's surface in bands or parallel zones, corresponding in a great measure with the peculiarities of temperature and climate which are appropriate to the nature of each. When the temperature of a particular latitude becomes colder, as on mountains or highly elevated plains,—or warmer, as on plains by the sea shore, or in low lying sheltered valleys,—we find, in the former case, that the species approximate in their nature and characters to those of a more northern, in the latter to those of a more southern parallel. Of course the zones of vegetable and of animal life do not correspond at all strictly with the *latitudinal* lines of our geographical system. Humboldt has indeed shown, that within 15° or 20° from the equator, the mean annual temperature is nearly the same in all longitudes of equal elevation, or is at least but slightly varied by local circumstances. In other words, the isothermal lines are more regularly parallel with those of the equator. But in temperate and northern countries the same uniformity of temperature in each portion of the same parallel is not observable; all western coasts, and districts of continents and of considerable islands, being of a higher temperature than those of the same latitudes along the eastern shores. The mean temperature of the North Cape, under the seventy-first degree of north latitude, does not exceed, indeed corresponds with, that of Labrador, which is 14° further south; and that of the west of Ireland, in the fifty-fourth degree, agrees with the forty-third parallel in the United States.

Geographical Distribution.

In relation to zoological geography, indeed, there are several other minor circumstances which tend to change or counterbalance the more usual results, and consequently to derange such calculations as might very reasonably be formed upon a knowledge of latitudinal and longitudinal position, and of the height of a country above the level of the sea. The nature of the soil and surface, the different degrees of dryness and humidity, and the consequent character of the climate and vegetation, the comparative extent of land and water, the extent and continuity of forests, marshes, and sandy deserts, the direction of mountain ranges, and the form and position of lakes;—these and several other circumstances must be taken into consideration, and will be found materially to affect the distribution of animal life over the surface of the earth.

It does not appear that the climates of insects, or those peculiarities of temperature and other physical attributes under which certain groups or species appear to predominate, have been as yet studied in connection with our imperfect knowledge of isothermal lines. Humboldt, indeed, has remarked, that the geographical stations of the gnats and some other insects of South America did not appear to depend solely on the *heat* of the climate, the excess of humidity, or the thickness of the forests, but on local and unappreciable circumstances.[1] It is evident, however, that the characteristic stations of insects are mainly dependent on the degree of temperature, so influential on the development and distribution of all the other varied forms of animal life. An increase of caloric seldom fails to produce a corresponding increase and alteration in the number and character of entomological forms; and when we travel from the hyperborean regions towards the sunny south, we find that the tiny multitudes accumulate in all the warmer portions of the temperate zone, till they swarm between the tropics. Otho Fabricius resided six years in Greenland, and during that period he collected only sixty-three species of the insect class, properly so called. In the still higher latitude of Winter Harbour, where Sir Edward Parry sojourned, only six species were collected from the beginning of September till the August following. Mr Kirby has stated that in Greenland every order of insect has its representatives, except Orthoptera and Hemiptera; but in Melville Island, besides these deficiencies, neither coleopterous nor neuropterous species exist, or at least were observable; and even the mosquito, that shrill tyrant of the Lapland plains, appeared to have ceased from troubling along those hyperborean shores. The most northern locality of any insect yet ascertained is that of the *Aphis borealis*, taken in latitude 82° 26′ 44″, about one hundred miles from the nearest known land.[2] It is probable, however, that the distribution of many northern species is still unknown. It was formerly supposed that in Iceland there were none, and that even in Norway there were very few, their absence from those countries being attributed to excess of cold. This opinion, however, was contradicted by Horrebow, so far as Iceland was concerned; and Olafsen and Povalsen, during their sojourn there, collected 200 different species in one small valley. It must indeed be borne in mind, that insects can escape the extreme of cold, not only, as Mr Macleay observes, by passing certain periods in the *pupa* or torpid state, but also by being while in that condition usually buried in the earth, where they are greatly protected from the rigours of the winter season. "What they chiefly re-

---

[1] *Personal Narrative*, vol. v. p. 88.

[2] This species was found in the boat during the last day of Sir E. Parry's attempt to reach the north pole over the ice. There was no vestige of vegetation around the adventurous party; and we think it more probable that the forlorn insect had been carried, *nolens volens*, from a somewhat more southern quarter.

Geographical Distribution.

quire is the presence of heat during some period of their existence; and the greater, within certain limits, is the heat, the more active will be their vital principle. On the American continent the extremes of heat and cold in the course of the year are, as is well known, incomparably greater than in places of the same latitude in Europe. We may therefore readily conceive how particular families of insects will inhabit a wider range of latitude in the former country than in the latter. We see also how insects may swarm in the very coldest climates, such as Lapland and Spitzbergen, where the short summer can boast of extraordinary rises in the thermometer; because the energy of the vital principle in such animals is, within certain limits, proportionate to the degree of warmth to which they may be subjected, and escapes in a manner the severe action of cold."[1] It is on these principles that Mr Macleay accounts for what certainly at first seems an extraordinary circumstance in the geography of insects; namely, that their tropical structure extends much farther north in America than in Europe; that is, in a manner directly the reverse of that which has been noted by botanists to occur in the vegetable kingdom. For example, the *Chamærops humilis*, a species of palm, occurs along the southern shore of France, in latitude 44°; while on the eastern coasts of North America the hardiest of the family, *C. palmetto*, does not advance beyond the 34°. But if we examine *Copris carnifex*, *Cetonia nitida*, *Rutela* 6 *punctata*, and other coleopterous insects from the neighbourhood of New York, and compare them with species of the same families from Brazil, we shall find their difference of structure infinitely less than that which would result from a comparison of the entomological productions of the environs of Madrid with those of the banks of the Congo.[2]

A slight consideration of the subject suffices to show that certain differences in the relative intensities of summer and of winter must exercise a strongly modifying power on the influence of mean annual temperature, even in countries where that temperature is one and the same. "Several fruits, as the olive and grape, as well as the different kinds of corn and other annuals, depend more on the heat of summer than of the whole year; while others, impatient of cold, and not requiring great heat, have their range more influenced by the temperature of winter. Now, it is almost an universal rule, that of two places whose mean temperature is the same, that nearest the sea, and more particularly a western sea, has a temperate summer and a milder winter. Hence the inland situation is better adapted to the growth of corn and fruits, the maritime one to the preservation of tender plants. In Europe, the northern boundary of the vine and olive rises as we go eastward, though in so doing we encounter a lower mean annual temperature. The *Arbutus Unedo*, *Sibthorpia Europæa*, *Erica ciliaris*, &c. rise in a westerly direction."[3] Whatever vegetation requires the absence of extreme cold rather than the presence of extreme heat, will probably extend itself in a tropical form more towards the poles on a dry continent than on a moist or marshy one. Tropical plants, therefore, will thrive better in Thibet and other inland parts of northern Asia, than they would do if transported to positions of the same latitude in America; for in the latter country the extremes of heat and cold are too distant from each other. Thus the vegetation of Canada does not correspond either in its general character or its amount of species, with that of the corresponding latitudes of France.[4]

Mr Macleay admits, that although in his opinion the insect tribes suffer less in cold climates than plants, for the reasons which we have already stated, it does not therefore follow that the prevalence of cold has no effect in relation to the destruction, or rather we should say the prevention, of insect life. In truth the diminution of the number of species becomes very conspicuous as we advance towards the poles. But this the learned author of the *Horæ Entomologicæ* supposes to be owing rather to the short continuance of the summer warmth than to the lowness of its existing degree. In accordance with this view we certainly find that many insects, such as gnats, mosquitoes, &c. which pass their larva state in water,—thus avoiding the external cold, and whose existence in the perfect state being naturally ephemeral, must therefore suffer little from the shortness of summer,—are nowhere more troublesome than among the moors and marshes of the north. On the other hand, the number of *coleopterous* species, which, being naturally longer lived, require a greater continuance of warmth, is sensibly diminished amid those dreary wastes.

It is natural to suppose that if certain plants are peculiar to certain climates, so also insects, the greater proportion of which not only feed on plants, but are each according to its kind almost restricted to particular species, must in like manner be characteristic of special localities. Whether this restriction in diet holds good in relation to the carnivorous kinds, that is, whether one kind of carcass is not as good as another, is a point which has not yet attracted the consideration of the naturalist. Such as feed on living animals (the *thalerophagous* Carnivora) are probably more restricted in their parasitical attachments. But the coprophagous or dung beetles, and such as prey on dead animals (the *saprophagous* Carnivora), may be supposed to be less regular in the limits of their localities, occurring wherever their favourite food happens (not seldom accidentally) to have been deposited. In such cases, of course, less advantage results to the entomologist from local references, as the appearance of an insect in the place cited may have been entirely accidental, and incapable of affording any great probability of its recurrence; yet even the saprophagous beetles are no doubt regulated by temperature and elevation, and it is likely that a dead body by the sea shore will exhibit different species from a similar nidus exposed on a mountain summit.

The geographical distribution of insects in general is, in truth, a subject of too difficult and complex a nature to admit of being worthily treated within our present limits. We shall, however, notice a few facts which, though presented in a somewhat desultory manner, we trust will not be found entirely devoid of interest.

We may observe, in the first place, that there are two aspects under which the subject of zoological geography may be viewed. We may either proceed upon the consideration of the divisions laid down by politico-geographical writers,—divisions which are no doubt sufficiently arbitrary in relation to the physical qualities of countries,—and describe or indicate the species and genera which we have ascertained to characterize such divisions,—or we may take into view the systematic arrangements of naturalists, and by tracing and pointing out the different localities of the various tribes, genera, and species which we find there arranged, thus arrive by another route at the conclusions sought for. We shall here, even at the risk of appearing immethodical, combine, in some measure, both these processes; and while we indicate the varied localities of certain species, we shall also give an occasional sketch of the equally varied entomological productions of particular portions of the earth's surface.

---

[1] *Hor. Ent.* p. 45.

[2] *Ibid.*

[3] Watson's *Outlines of the Geographical Distribution of British Plants.* (Printed for private circulation.) Edinburgh, 1832.

[4] *Hor. Ent.* p. 44.

We formerly remarked that no coleopterous insect was noticed in Melville Island. *Dytiscus marginalis*, however, an aquatic beetle well known throughout Great Britain, inhabits the waters of Greenland, and extends over the whole of Europe. Another species of the same genus, *D. griseus*, is not only spread over the south of Europe, and most of the countries adjacent to the Mediterranean, but is also found in Bengal. The genus *Calasoma* is very widely spread. Captain Frankland took *C. calidum* during his arctic journey. *C. laterale* and *curvipes* inhabit tropical America; while *C. Chinense*, as its name imports, is found in China. Mr Macleay possesses a specimen from New Holland; and *C. retusum* was captured in Terra del Fuego. The *Coccinellæ* occur in almost all countries from pole to pole.[1] The *Silphidæ* and *Dermestidæ* prey on carcasses wherever the solar influence is of sufficient power to produce putrescence; but the brachelytrous beetles (genus *Staphylinus*, &c.) have undoubtedly their metropolis or centre of dominion in the temperate zone, and more especially within the British islands; for while Dejean, in the last edition of his *Catalogue* (1833), gives only 789 species as his total amount both of European and exotic kinds, Mr Stephens enumerates above 750 as indigenous to Britain. This apparent excess may, however, partly arise from the great attention which has been paid in this country to the collection of the minuter sorts, which are frequently neglected in foreign lands for the sake of the more showy and imposing species. The genus *Onthophagus* is native both to the old world and the new, to the temperate as well as the torrid zone; while *Copris*, its near ally, is more abhorrent of cold,—*C. lunaris*, which extends northward into Sweden, being the only recorded species found in Europe out of Spain.[2] Latreille, however, laboured under a misconception when he supposed that all the large species of the latter genus were of equinoctial origin; for *C. Tmolus* of Fischer occurs in the vicinity of Orenburg in Asia, under the 50th degree of north latitude.[3] Of the magnificent *Dynastidæ*, termed by Mr Kirby the "giants and princes of the insect race," the metropolis is strictly tropical, although a kind of advanced piquet is observable in *Oryctes nasicornis*, common in the south of Sweden. The reason why the last-named insect, and several others which occur in Scandinavia, are unknown in Britain, may be inferred from some of our preceding observations: in a torpid state, or under the form of larvæ, they are capable of enduring the utmost rigour of a Swedish winter; but when revived by the returning spring, the cool and variable summers of our "sea-girt isle" would prove insufficient for the full development of their vital functions.

The genus *Meloe* seems almost peculiar to Europe; and Britain, which possesses nine species, has been regarded as one of its most characteristic countries. The entomological characters of the southern shores of Europe strongly exhibit their geographical approach to the African continent. The *Ateuchus sacer* (the renowned species sculptured of old by the Egyptians on their sacred monuments), and various species of *Scaurus* and *Akis*, may be regarded in the southern countries of Europe, as the *avant couriers* among the coleopterous tribes of those more exclusively African forms which have their centre of dominion in the burning deserts. Along the Mediterranean shores the entomological traveller may study the habits of many curious insects of the genera *Onitis*, *Cebrio*, *Pimelia*, *Brachycerus*, *Brentus*, and *Scarites*, and may also enrich his collection by the capture of many beautiful butterflies, and other lepidopterous insects, which are more truly characteristic of Northern Africa. Spain especially exhibits many features of African zoology. We shall not here talk of the cameleons, the scorpions, and other species belonging to the separate classes of reptiles and Arachnides; but the European entomologist will there discover for the first time several species of the genera *Erodius*, *Sepidium*, *Brachinus*, and *Pimelia*. It is however only after crossing the Mediterranean, and traversing the African shores, whether north of the Atlas, or eastward towards the coasts of the Red Sea, that our eyes are delighted with the hitherto unknown forms of *Anthia*, *Graphipterus*, *Siagona*, and numerous other species unknown to the colder and moister shores of Europe.

But no sooner do we leave the Mediterranean coasts of Africa, and enter upon the more weary and disastrous pilgrimage of the great deserts, the apparently limitless expanse of which so soon greets the eye of the yet undaunted traveller, than almost all vestiges of European life, whether human or brute, disappear; and Nubia, Ethiopia, Senegal, and a great part of Guinea, exhibit entomological forms, cognate in character when compared among themselves, but separated in every sense of the words "*longo intervallo*" from those of Europe. As we proceed farther southwards, where the chariot of the "Great Apollo" rolls on with a still fiercer and more fiery lustre, and the beams of a vertical sun induce even the tawny Moor and the woolly-headed negro to avoid his scorching and sometimes fatal rays, we discover many extraordinary forms of insect life, called into existence through the instrumentality of that bright effulgence which the pale-faced European has so often sought to withstand in vain. From the burning regions of Guinea, and the parched shores of the Congo, we derive the finest of those magnificent coleopterous insects named generically *Goliathus* by Lamarck. The western and equinoctial parts of Africa also yield us the species of *Petalocheirus* and *Enceladus*, while the Cape of Good Hope is remarkable for the genera *Anthia* and *Brachycerus*. The last-named district is almost the exclusive domain of *Manticora* and *Pneumora*; and the southern parts of Africa present us with the *Sagra*, *Diopsis*, and *Paussus*, although it may be observed that some of these also occur in the East Indies.[4]

Both Madagascar and St Helena present a few insects which, to a certain extent, demonstrate the African complexion of those islands; but the latter especially is also allied, by its entomological features, to some of the south-western countries of Asia. According to Latreille, Africa furnishes no species of the genus *Passalus*, although it is elsewhere widely distributed over America and the East Indies. The genera *Graphypterus*, *Eurichora*, and *Pneumora*, are probably peculiar to Africa. Among the hemipterous insects of Africa may be mentioned the *Mantis precaria*, an object of superstitious veneration among the Hottentots, who hold in the highest respect the person on whom the insect happens to alight. Locusts are of common occurrence in many parts of Africa, where, as "a great people and a strong," they still produce their days of "darkness and of gloominess," their days "of clouds and of thick darkness," so magnificently described by the Prophet Joel. One of the most formidable of the insect tribes of this continent is the *Termes bellicosus*, or

Geographical Distribution.

white ant. It dwells in congregated troops, consisting of labourers, soldiers, and sovereigns. The habitations are of a conical form, built of mud and clay, from ten to twelve feet high, and divided in the interior by thin partitions into a variety of cells. Indeed, Jobson, in his *History of Guinea*, alleges that they are often twenty feet high; and he adds, that he frequently found them extremely serviceable in screening himself and his companions while engaged in the pursuit of antelopes and other game. The queen-mother of this species becomes of so enormous a size in the pregnant state, that her abdomen exceeds, by two thousand times, the bulk of the rest of her body; and when the ova are fully formed, she obtrudes them at the rate of sixty in a minute, or 72,000 in twenty-four hours. Madeira and the Canary Islands are decidedly African in their productions,—the insects, especially, exhibiting a strong relationship to those of Barbary and the adjacent districts.

Latreille, while considering the geographical distribution of insects, has well observed, that where the empire of Flora terminates, there the domain of zoology likewise comes to an end. Animals which feed on vegetables cannot support themselves in a region entirely sterile, and such as are carnivorous are thus themselves indirectly deprived of sustenance in consequence of the want of vegetation. Those countries of which the vegetable productions are the most gorgeous and abundant, are likewise the most productive of insect life. Both effects spring from a temperature high and continuously sustained, from moderate moisture, and a varied soil. The more closely, on the contrary, we approach the other extreme, where clouds and darkness obscure the sky, and the ground is so often covered with a pure but unproductive garment of snow, and the lifeless solitude of the mountain valleys is defended by the icy battlements of the enduring glaciers,—the more we shall perceive a diminution in the amount of organic, and more especially of insect life. If, instead of travelling northwards to the polar plains, we ascend some majestic mountain even of a tropical range, the same phenomena are observable. Although its base should be laved by the glittering waters of an equatorial sea, and its sloping sides should bear the arborescent ferns and plumy palm trees of the warmest climes,—still, should the mountain belong to the highest class, like those of Cayambé or Chimborazo, long before the traveller has approached its barren summit, he will perceive the most striking symptoms of that sterility which we are apt to associate only with the polar regions. The "bright consummate flowers" of the lower plains have disappeared,—the parrots in their gay attire no longer adorn the stunted trees,—and the insect tribes, so fantastic in their forms, and of such surpassing lustre, have gradually decreased in size and number, and at last present, in common with the vegetable kingdom, an aspect and character much more allied to those of northern climes. Finally, unless it may be that some giant condor, or other bird of loftiest flight, is seen floating in the thin air of those extremest heights, there is nothing to remind the adventurous traveller that he is actually within the *burning* tropics; for all his perceptions and sensations might be identical were he suddenly transported to the summit of Mount Hecla,

> An earthquake-rifted mountain of bright snow.

It is thus that, on the Central Alps of Europe, we meet with many species characteristic of, though not peculiar to, the plains of northern countries. The *Prionus depsarius*, long regarded as exclusively confined to Sweden, has in later times been taken on the mountains of Switzerland; and M. Latreille has captured at Cantal the *Lycus minutus*, formerly received only from the most northern provinces of Europe. The beautiful Apollo butterfly (*Parnassius Apollo*), so common in the plains and flower-gardens in the vicinity of Upsal, never occurs in France, except on mountains of considerable elevation, and re-appears again in the snow-surrounded valleys of Switzerland. Many other butterflies which, in the northern provinces of France, occur not far from warm and low-lying sheltered stations, are found in the southern departments and in Italy on alpine or sub-alpine situations. The same may be said of *Carabus auratus* and *Acridium grossum*. Even in Great Britain, the limited extent of which might be supposed to preclude any great disparity in the entomological productions of its geographical divisions, there is an obvious difference between its southern and northern quarters. The colder and more cloudy clime of Scotland is poor in Lepidoptera of the finer kinds. Here no purple emperor, "proud of cerulean dyes," floats over the far-stretching branches of our oaks and beeches,—no swallow-tailed butterfly (*Papilio Machaon*), with its elegantly lengthened wings, reminds us of the exquisite Brazilian tribes,—no "Camberwell beauty" (*Vanessa Antiopa*) expands to the sun its richly margined wings; but these and many more, denied to bleak Caledonia, are found in the southern counties of England.[1] It is interesting, however, to observe the analogy which exists between the insects, more especially the Coleoptera of Scotland and of Sweden. Several of the rarest species lately discovered in the northern quarters of the island, such as *Clivina Arctica*, *Harpalus micropterus*, *Elaphrus Laponicus*, *Byrrhus æneus*, *Salpingus foveolatus*, and others, are better known in the Scandinavian peninsula than elsewhere, and are indeed characteristic of the north-western division of the continent of Europe.

From these and similar observations, those who have viewed the science of entomology with a philosophic eye have endeavoured, in common with geographers, to divide the surface of the earth into different climatic regions. But while the latter have assumed as a basis the progressive differences in the longest continuance of the natural day, the former proceed upon a knowledge of the mean temperature of countries. Fabricius, in his *Philosophia Entomologica*, divides climate in general into eight subclimates, or restricted stations, viz. the *Indian*, the *Southern*, the *Mediterranean*, the *Northern*, the *Eastern*, the *Western*, and the *Alpine*. But it is easy, as M. Latreille has remarked, to perceive, by the enumeration of the particular countries which are referred to each of these divisions, that the divisions themselves are by no means established on a fixed foundation; and that the suppression of several would be necessary were the principle on which they are established followed out with rigour. The subclimate which he names *Mediterranean* comprises the countries adjacent to the Mediterranean Sea, with Media and Armenia. The *Northern* extends from Paris to Lapland. The *Eastern* consists of the north of Asia, of Siberia, and of the cold or mountainous portion of Syria. The *Western* contains Canada, the United States, Japan, and China. From these it will be seen that this arrangement is in many respects extremely arbitrary; for several of the above-named districts, although placed under separate climates, have a mean temperature identically the same. Moreover, many countries in which the mean temperature is the same, are characterized and distinguished

---

[1] On the other hand, *Hipparchia Blandina* and *Lycæna Artaxerxes*, two extremely rare English butterflies, occur very plentifully in many parts of Scotland,—the former in July and August, the latter in June and July.

Geographical Distribution.

by a great disparity in the nature of their animal productions.

M. Latreille has taken another view of this interesting subject, more in conformity with the dictum of Linnæus, regarding the characters of genera, the spirit of which may be also here applied. "Let the insects point out the climate, and not the climate the insects." He takes into consideration all those genera which seem to be appropriated exclusively to certain determinate spaces on the surface of our earth. It is true that the groundwork of this method is much more restricted than that from which Humboldt and other writers on botanical geography have deduced their observations on the distribution of plants; for our knowledge of the precise localities of foreign insects is by no means ample.[1] The great French entomologist rather upbraids the majority of scientific travellers with their negligence in these particulars; for it is not the locality alone, but the physical character of the climate, the mineralogical qualities of the soil, the vicinity of wood and water, and the height above the level of the sea, which ought to be noted in connection with the occurrence of particular species. We have already noticed the fondness of *Papilio Cleopatra* and other insects for a calcarcous soil. The *Pimelia bicaudata*, so common in the neighbourhood of Marseilles, scarcely ever occurs at a distance from the sea. If the interior parts of Barbary, Syria, and Egypt, present us with species of the same genus, this entomological relation no doubt results from the soil of these countries being impregnated with saline particles, and abounding in plants of the genus *Salsola.* The insects which occur in the countries which border the Mediterranean, the Black, and the Caspian Seas, exhibit many analogies.

The following propositions result from M. Latreille's researches in Entomology.

1*st*, The totality or a great proportion of the insects which occur in countries of which the qualities of the soil and temperature are analogous, are nevertheless of different species, if these countries, though placed under the same parallel, are widely distant from each other. All the insects brought from the most eastern parts of Asia, for example China, are distinct from those of Europe and of Africa, whatever may be the latitude, elevation, or mean temperature of these Asiatic countries.

2*d*, The generality of insects still differ specifically in countries agreeing in the characters of their soil and temperature, but separated, independently of mere latitudinal difference, by great natural barriers, such as chains of lofty mountains, vast sandy deserts, or the waters of an intervening ocean. Thus the species of New Holland or of America are easily recognised among those of the various countries of the ancient world; and even the insects of Grenada and Peru, though at no great distance from those of Guiana, are in a great measure different, owing no doubt to the interposition of the vast chain of the Cordilleras. When we pass from Piedmont into France by the Col de Tende, we perceive a marked difference of species, even in that short journey. These rules, however, like most others, however general, are subject to several individual exceptions. Several species of insect are distributed over such a vast extent of territory as entitles them to be regarded as genuine cosmopolites. Thus the painted lady-butterfly (*Vanessa Cardui*) is found over great portions of Europe, Asia, Africa, and America, and is as familiarly known in the central islands of the vast Pacific Ocean, as in the flower-gardens of England.[2] That beautiful sphinx-moth (*S. nerio*), well known near Genoa, and so remarkable for the richness of its *green*, a rare colour among lepidopterous species, although it seldom occurs farther north than France, is found in the Mauritius, and probably in many intermediate countries. The deaths' head moth (*Sphynx Atropos*), which occurs occasionally in most parts of Scotland, is well known in India and the Isle of France. We have already mentioned the great extent of territory occupied by several aquatic beetles; and these and other examples which might be adduced remind us of M. Latreille's next proposition.

3*d*, Many *genera* of insects, and particularly such as feed on vegetables, are spread over numerous points of the principal divisions of our globe.

4*th*, Other genera are exclusively proper to a certain extent of country, whether of the ancient continents or the new. According to Latreille, no species of the genera *Anthia, Graphipterus, Erodius, Pimelia, Scaurus, Cossyphus, Mylabris, Brachycerus, Nemoptera, Apis*, or *Anthophora*, occur in America; and many genera of the family *Scarabeidæ* are likewise there unknown. But the western world, on the other hand, produces several genera which we do not meet with elsewhere,—such as *Agra, Galerita, Nilio, Tetraonyx, Rutela, Doryphora, Alurnus, Erotylus, Cupes, Corydalis, Labidus, Pelicinus, Centris, Euglossa, Heliconia, Erycina, Castnia*, &c. Our bees are there replaced by *Melipona* and *Trigona*. We have already mentioned several genera peculiar to Africa. *Colliuris* is characteristic of the East Indies; *Lamprima, Helæus, Paropsis* (*Notoclea* of Marsham), and *Panops*, are confined to New Holland.

5*th*, Many species in their natal countries effect particular localities. Several alpine butterflies are never observed at any considerable distance from the region of perpetual snow, while other species prefer the warmer air of low-lying sheltered meads at no great height above the level of the sea.

6*th*, Both the ancient continent and the new may be divided into zones, successively extending in the direction of the meridians, and the breadth of which is measurable by a portion of a circle parallel to the equator. The species proper to one of these zones disappear gradually, and give place in the same manner to those of the zone following; so that from space to space the dominating species, or even the totality, have undergone a change.[3] Latreille compares these changes to that series of horizons which the traveller discovers in proportion as he removes from his first point of departure.

Sweden presents us with many insects peculiar to that country, some of which are confined to its more northern provinces, such as Lapland. But its southern portions, for example Scania, produce, though still in limited numbers, many German insects. France, as far as the 45th or 44th degree, supplies the entomologist with many of the species which occur in the last-named countries; but the Rhine and its eastern mountains form a kind of frontier line, which many others do not appear to pass. The first of the species characteristic of the warmer regions of

Nat.* It was afterwards republished, with corrections and additions, along with some other essays, in a separate volume, entitled *Mémoires sur divers Sujets de l'Histoire Naturelle des Insectes*, &c. Paris, 1819.

Geographical Distribution.

Western Europe show themselves towards the inferior course of the Seine, in pretty close accordance with the point where the vine is vigorous in the open air, independent of any succour derived from merely local circumstances. *Ateuchus flagellatus, Mylabris chicorii, Mantis religiosa, Cicada hæmatodes, Ascalaphus italicus,* and others, announce this change,—which becomes still more obvious at Fontainebleau and the environs of Orleans, where, in addition to the above-named species, we may perceive *Phasma Rossii, Mantis pagana,* and *Sphinx celerio.* But these are but the forerunners of such as are native to southern countries properly so called. The culture of the olive, the spontaneous growth of the Arbutus, the pomegranate, and of lavender, are botanical symptoms which cherish in the mind of an instructed entomologist the hopes of a rich increase. This change is very obvious in France, when, journeying from Paris to Marseilles, we reach the territory of Montélimart. The eastern provinces of Spain, those sunny regions where the orange and the palm-tree are luxuriant without the aid of man, produce more abundantly the rarer southern insects of France, intermingled with species hitherto unperceived in Europe.

Our knowledge of the insects of the south-east of Europe is by no means ample. Latreille informs us that the *Papilio chrysippus* of Linnæus, common in Egypt and the East Indies, makes its first appearance as a European species in the kingdom of Naples. The greater proportion, however, of the Egyptian species are entirely unknown in Europe, although they pertain, in numerous instances, to the same natural families as our own. The southern parts of that land of pyramids produce many magnificent species of *Copris,* such as *C. Midas, Bucephalus, Antenor, Gigas,* and other insects peculiar to warm countries, and seldom found at any great distance from the equinoctial line of the old continent.

Similar successions of species take place from east to west, and reciprocally. Most of the insects which occur in Normandy and Brittany likewise inhabit the southern parts of England. The northerly departments of France, situated on the banks of the Rhine, have in many respects a community of species with the neighbouring provinces of Germany; while, again, several species of the Levant, such as *Cantharis orientalis, Mylabris crassicornis,* a beautiful variety of *Melolontha occidentalis* brought home by Olivier, and certain diurnal Lepidoptera, appear to have journeyed far westward from their ancestral homes, and fixed their abode in the Austrian territory. The collections formed by Olivier in Asia Minor, Syria, and Persia, prove that the insects of those countries, though nearly related to those of the south of Europe, are not specifically the same; and a like judgment, with some exceptions, may be entertained of the species of Southern Russia and the Crimea. The entomological productions of the coast of Coromandel, of Bengal, of the south of China, and even of Thibet, possess many characters in common; but they are entirely distinct from those of Europe. In the regions just named we discover no species of the genera *Graphipterus, Akis, Scaurus, Pimelia, Sepidium,* or *Erodia,* for of these nature appears to have granted the exclusive possession to the south-western regions of the ancient continent. Although Fabricius assigns the East Indies as the native country of certain species of *Brachycerus,* Latreille has been unable to identify any from such locality. The genus *Anthia* is said to occur in Bengal, but not farther eastward.

The great Asiatic division of our globe, when considered in its entomological and other zoological relations, may indeed be partitioned into several different departments.[1] The Siberian or most northern portion, in consequence of the severity of its winter season, possesses, even in its southern districts, many attributes of the arctic regions; while its inland valleys, and the upper basins of its numerous and far-flowing rivers, are enriched, during a brilliant though short-lived summer, with many of the more gorgeous forms of insect life. Another vast and imperfectly known region of Asia is bounded to the north by Siberia, and to the south by those highly elevated table-lands which terminate among the Himalaya Mountains. This division still presents several features which prove its assimilation in some respects to the characters which distinguish animal life in Europe; for although it is undoubtedly characterized by numerous peculiar forms of existence, yet many of its genera and species are either the genuine types of groups which occur in countries with which we are familiar, or pertain to groups which are themselves well exemplified by European insects. But we now speak rather in relation to the higher animals than the insect tribes; for, in truth, of the Entomology of Central Asia we have as yet a most inadequate idea. Among the Himalaya Mountains, and other southern portions of this division, we begin to discover many genera of birds which occur in the lower lands of Hindustan and the peninsular projection of Malacca; and if the entomological kingdom is at all regulated by corresponding rules, we may infer that some of the southern insects also make their way up those stupendous valleys. The same circumstance indeed occurs, we mean the like transition of species, in all the great geographical sections of the groups of animal life. "Each extensive division is characterized by several peculiar forms, and yet at the same time nourishes many species which are common alike to it and to other regions; and it is only under some peculiar circumstances of local situation, that either the zoological or botanical products undergo a sudden change in character and condition. As the adventurous and observant traveller advances on his journey, a few species are continually perceived to decrease in number, and then to disappear, while their places are supplied by others, which, at first but thinly scattered, gradually acquire an accession of numbers, till they too have reached their full amount or centre of dominion; but the change being only partial from place to place, the difference is no more suddenly perceptible than that in the horizon by which the traveller is surrounded, and a portion of which in his onward progress becomes insensibly, from the circumference, the very centre of the field of vision."[2] But no sooner do we enter upon the zoology of India Proper, than the European forms of animal life almost entirely disappear, and are succeeded by others of a richer and more varied character of form and aspect, some of which, however, extend to the parallel latitudes of the African continent. The Asiatic Islands again present us with another picture, and this latter change may be said to commence at the southern extremity of the Isthmus of Malacca. Java and Sumatra, in Mr Swainson's opinion, will probably be found to be the metropolis or central region of this range, which still produces several of the forms of Northern India; while in New Guinea and New Ireland, the Asiatic forms properly so called begin to disappear, and are replaced by many singular and interesting species, which exhibit the commencement of what may be termed the Australian kingdom. *Papilio bolina* occurs both in Java and New Holland.

Madagascar, as might be supposed, exhibits in its natu-

---

[1] *Edinburgh Cabinet Library*, vol. viii. p. 1.

[2] *Ibid.* p. 2.

Geographical Distribution.

ral families a resemblance to Africa. Nevertheless the species are distinct, and many of them present no analogy whatever to those of the continent. The Isles of France and Bourbon likewise manifest traces of the same family resemblance; but, on a general view, they show a closer connection with the East Indian species. Their ascertained number is, however, extremely limited.[1]

Although the Entomology of New Holland may be said, like that of all other vast tracts of country, to exhibit a special type, it is yet composed, in some of its principal portions, of species analogous to those of the Moluccas and the south-east of India. This great fifth continent, as it has been called, is, however, less rich in insects than many other foreign countries, its soil being drier, and not so well wooded. The genus *Mylabris*, so abundant in the south of Europe, in Africa, and Asia, does not appear to pass beyond Timor. In that respect, then, New Holland agrees with America, as well as in the possession of *Passalus*, a genus of which the species have been more particularly noted as inhabitants of the new world. Several generic groups of the latter region present a closer resemblance to those of the east of Asia, than to such as are characteristic of the ancient world. The insects of New Zealand, of New Caledonia, and the circumjacent isles, show an obvious relation to those of New Holland; and the same may be said of such as occur in the archipelagos of the Great Southern Ocean. These islands, composed in great measure of aggregations of polypiferous rocks, form a chain which unites them in a westerly direction to the preceding regions, and from which many of their natural productions may have been received in the long course of ages. This natural communication could not have taken place with the new world, and thus many of these islands, although rather American than otherwise, according to their geographical position, may be regarded as Asiatic in regard to their animal and vegetable products.

The new world has also been observed to present progressive changes in the succession of its species, in connection with every considerable difference in the latitude and longitude. M. Bosc collected in Carolina many species which were unknown in Pennsylvania, and were still more foreign to New York; and the researches of Abbot in illustration of the Lepidoptera of Georgia demonstrate the existence in that province of certain species which have their central station in the Antilles. The banks of the far-stretching Missouri, about twenty degrees to the west of Philadelphia, produce many peculiar species. The Entomology of the Antilles presents a strong contrast to that of the United States. Trinidad, under the tenth degree of north latitude, presents us with truly equatorial species, such as the splendid butterflies called Teucer and Menelaus, which do not occur in St Domingo. Brazil, so gorgeous in its insect tribes, possesses species in common with Cayenne, but it also produces many others peculiar to itself. Latreille differs from Mr Macleay in his opinion regarding the comparative extension, in a northerly direction, of the southern species in the new and old world. He states that the southern species of the western hemisphere do not attain to so high a latitude as they do on the ancient continents. Here, he thinks, they begin to appear between the forty-eighth and forty-ninth degrees of north latitude; there, not until we gain the forty-third degree.[2] In relation to this subject Mr Kirby has remarked, that although the winters in Canada, within the same parallel as France, are longer and more severe than those even of Great Britain or of Germany, yet the summers are intensely hot; so that though tropical *species* do not range so high, those of a tropical *structure*, in conformity with Mr Macleay's views, may be found in a higher latitude in the new world than in Europe.[3] When we take into consideration certain peculiarities in the physical constitution of America,—its well watered surface, its lofty mountains, its majestic forests, and humid atmosphere,—we shall easily understand how many genera of the ancient continent, dwelling by preference in dry, warm, and sandy situations, for example *Anthia*, *Pimelia*, *Erodius*, and *Brachycerus*, should not occur in the comparatively rich, moist, and shaded soils of the new world. Thus also the carnivorous Coleoptera in America are proportionally of smaller amount than in the old continent, although no quarter of the globe is more productive of large and splendid species among the phytophagous or vegetable-eating tribes of insects. However, the south of China and the Moluccas still maintain a certain superiority in the production of such splendid examples of the lepidopterous order as *Papilio Priamus* and *Bombyx Atlas*, of which the dimensions surpass those of the American species. A fact noted by Latreille is worthy of remembrance, viz. that Europe, Africa, and Western Asia, are extremely unproductive of the genus *Phasma*, or the spectre insect, and that such of the species as do occur are extremely small, while the Moluccas and South America produce many of remarkable size. The atmospheric humidity of the new world, its narrow and elongated form, the nature of its soil, and the vast extent of ocean by which it is environed, are sufficient reasons for the disagreement observable between its productions and those of corresponding latitudes in our own hemisphere. The new world, in fact, bears in many respects the same relation to the old that Britain does to a great portion of Europe.[4]

We have already alluded to the classification of climate given by Fabricius, and to certain circumstances which have been supposed to render the adoption of that classification unadvisable. Latreille has viewed the same subject under a better aspect. He considers the northern extremities of Greenland and of Spitzbergen, under the eighty-first degree of northern latitude, as the points where vegetation terminates. But to obviate all difficulty, and with a view to establish a duodecimal division, which is not only convenient in itself, but also in frequent accordance with the actual observation of geographical groups, he raises this supposed limit of vegetation three degrees higher, that is, to the eighty-fourth degree. If we then divide into successive spaces of twelve degrees, a meridian commencing from the western parts of Spitzbergen, or those nearest to Greenland, we shall have a suite of latitudes corresponding successively to the limits of the countries already alluded to in relation to their zoological productions. He continues these sections duodecimally or by twelve degrees, beyond the equator, and towards the antarctic pole, and stops about the sixtieth degree of southern latitude, under the parallel of Sandwich Land, regarded in that direction as the *ne plus ultra* of geographical discovery.

It appears that a difference in latitude of twelve degrees always produces a very sensible change in the mass of insect species; and that if that space is doubled, the alteration is almost total; as, for example, between the

Geographical Distribution.

north of Sweden and the north of Spain. An analogous change takes place in relation to the *longitude*, but more slowly, and after a traverse of a greater distance; since the mean temperature, but for causes of a particular and local nature, is not widely different under the same parallel. In proportion as we approach the pole, the extent occupied by particular races embraces a greater number of geographical divisions.

The insects of America, even those of its northern provinces, at least as far as Canada, may be said to differ specifically from those of Europe; but the species of Greenland may rather be regarded as European. The last-named country, so far as the entomological geography of the ancient continent is concerned, is assumed by Latreille as the point of departure for his first meridian. In any view it may be regarded as intermediate between the two hemispheres. The Canaries, the Cape de Verd Islands, and Madeira, are African, judging from their entomological productions. The meridian above named will thus follow a middle line between these islands and the most eastern cape of South America, that of St Roque, near Rio Grande, in Brazil. It will pass by the western isles, or archipelago of the Azores, and by the island of Ascension, and will abut to the westward of Sandwich Land. Its longitude will be thirty-four degrees to the west of the meridian of Paris. According to Latreille's observations on the insects collected by Olivier in Persia, their general relationship to those of the south of Europe and the north of Africa, and the essential differences which they present when compared with the entomological productions of the East Indies, it may be inferred that the most signal changes in the species take place in a southerly direction towards the frontier lines of Persia and Hindustan, and in a northerly direction at a short distance from the eastern slopes of the Uralian Mountains and Lake Aral, a little beyond the sixtieth meridian east of Paris. We may fix this limit approximately at sixty-two degrees, somewhat to the west of the Obi, and of Balk and Candahar, for the sake of affording the means of continuing a duodecimal division; for if we add 62 to 34, the difference between the first meridian and that of Paris, we have the number 96, a quantity susceptible of being divided, without fractions, into eight parts, each equal to the thirtieth portion of the circle. We thus separate the ancient continent into two great bands, of which one is western and the other eastern; and if we assign to the latter the same extent in longitude as the former, that is, ninety-six degrees, it will terminate 158 degrees of eastern longitude from the meridian of Paris. Departing from Kamtchatka, it will pass by the Carolinas, and from thence between New Holland and New Zealand. If augmented by one fourth, or by twenty-four degrees, this eastern band would be bounded by the 182d meridian east of Paris, and passing at a short distance from East Cape, over Behring's Straits, would stretch beyond the Friendly Islands, and form, without any material error in relation to our entomological views, a line of demarcation between Asia and America. The remaining 144 degrees complete the equatorial circle, and compose the extent in longitude of that great zone proper to the insects of America. It may also be divided, and under the same denominations of eastern and western, into two equal portions, each of seventy-two degrees. Thus the entire circle of the equator may be regarded as divisible into four arcs, of which the values are, 72, 72, 96, and 120, or in the proportion of six thirtieths, eight thirtieths, and ten thirtieths. The extent in longitude of the ancient continent will comprise 216 degrees, and that of the new 144.

The lesser zones or climates are denominated *arctic* or *antarctic* by M. Latreille, according to their position on this or the other side of the equator. The climate included between the 84th and 72d degrees of north latitude is named the *polar* climate. Then follow as far as the equator, and always in divisions of twelve degrees, the following climates, viz. the *sub-polar*, the *superior*, the *intermediate*, the *super-tropical*, the *tropical*, and the *equatorial;* and as each hemisphere is partitioned into two great divisions, the climates of each are distinguished by the name of western and eastern. The antarctic climates consist of only three in number, as we know little of what exists amid those chilly regions beyond the 60th degree of south latitude, and thus in that direction both the polar and sub-polar climates may be suppressed. We shall illustrate these views by a few applications to the northern and western kingdoms of Europe, the best known portions of the old world.

The *polar* climate presents us with the insects of the greater part of Greenland, and with those of Iceland and of Spitzbergen. In the *sub-polar* climate we shall find those of Norway, of the north of Sweden, and of Russia in Europe. These two of course contain the insects of the coldest climates of the earth. We may regard as belonging to the *superior* climate the species of Great Britain, of the south of Sweden, of the north of France as far as the inferior course of the Loire, of Prussia, of Germany Proper, and of the south of Russia as far as the Crimea exclusive. The *intermediate* climate, at equal distances from those of the equator and the pole, will comprehend all the species of the south of Europe, and of a portion of the west of Asia. Those of the north of Africa, and as far as the equator, may be classed under the climates called *super-tropical*, *tropical*, and *equatorial.* These western climates may be divided into two equal parts, each consisting of forty-eight degrees, by a meridian which, passing fourteen degrees to the east of Paris, in the vicinity of Vienna, would leave to the east the most southern part of Italy, Turkey in Europe, Egypt, &c. Now it has been already remarked, that many of the insects of the environs of Vienna are also known to occur in the Levant, and that those of the kingdom of Naples, of Egypt, and of the south-east of Europe, appear to differ in many respects from the southern and western species of that division of the globe. We can here, then, effect the formation of sub-climates. If we divide the eastern portion, of which the extent in longitude is 120 degrees, into four equal sections of thirty degrees, by meridians, we shall have sub-climates, of which the boundaries seem very accordant with nature. Thus the first would comprehend Hindustan, Thibet, Little Bucharia, &c. while the second would detach almost all the Philippine Islands, China Proper, and the regions of the north as far as a short way beyond the river Lena. Corea, Japan, and the countries of the Manchous and Tongouses, &c. would form the third subdivision. The fourth would present Kamtchatka, and the other countries which terminate the north-east of Asia. America may likewise be subdivided after a similar manner.

It must, however, be borne in mind that nature, in her distribution of the localities proper to the various races of animals, often swerves from her more regular and accustomed courses, and that the *lines of habitation* form numerous curves and sinuosities, not unfrequently crossed or interrupted by others of a somewhat different nature. We must, therefore, in considering such views as the preceding, make abstraction of particular modifications which alter or derange our theoretical views. Latreille's is but an unfinished sketch of a highly interesting geographical map of Entomology, in which he has endeavoured, as well as he could, to mark out various boundaries, and to divide them according to certain principles in harmony with his actual observations, so far as these have been hitherto carried. The geographical distribution of living beings presents a wide field for speculation, although the modes by which that distribution has been effected will probably in many cases remain for ever concealed from human knowledge. Their gradual extension by natural means, from a single centre of creation, scarcely falls within the sphere of credibility; and thus the creation of various groups of species over different points of the earth's surface, and in accordance with the climate and physical character of different countries,—or the removal and dispersion, by supernatural agency, of the greater proportion of existing species from an original centre,—seem the two points, one or other of which remains to be illustrated by whoever is curious in such bewildering speculations. "A glance at the innumerable and far-spread legions which compose the busy world of insect life renders the subject still more complex and confounding. A discovery ship, under the guidance of brave men, surmounts with difficulty the terrors of the ocean; and, after being months on the trackless main, and some thousand miles from any of the great continents of the earth, she arrives at last and accidentally at some hitherto unknown island of small dimensions, a mere speck in the vast world of waters by which it is surrounded. She probably finds the 'Lord of the Creation' there unknown; but though untrod by human footsteps, how busy is that lonely spot with all the other forms of active life! Even man himself is represented not unaptly by the sagacious and imitative monkeys, which eagerly employ so many vain expedients to drive from their shores what they no doubt regard as merely a stronger species of their race. 'Birds of gayest plume' stand fearlessly before the unsympathizing naturalist; and at every step of the botanical collector the most gorgeous butterflies are wafted from the blossoms of unknown flowers, and beautify the 'living air' with their many splendid hues. Yet how frail are such gaudy wings, and how vainly would they now serve as the means of transport from that solitary spot, where all the present generations have had their birth! In what manner, then, did they become its denizens, or by what means were they transported to a point almost imperceptible in comparison with the immeasurable extent of the circumjacent ocean?"[1]

In the opinion of Humboldt, the causes of the distribution of species, whether in the vegetable or in the animal kingdom, are among the number of mysteries to which natural science cannot attain. This science, or at least that branch of it which takes cognizance of zoological geography, is not occupied in the investigation of the origin of beings, but of the laws in accordance with which they are now distributed over the surface of the earth. It enters into the examination of things as they are, the co-existence of vegetable and animal forms in each latitude, at different heights, and at different degrees of temperature; it studies the relations under which particular organizations are more vigorously developed, multiplied, or modified; but it approaches not problems the solution of which is impossible, since they touch the origin or first existence of the germs of life. "We may add," says that enlightened naturalist, "that the attempts which have been made to explain the distribution of various species over the globe, by the sole influence of climate, date at a period when physical geography was still in its infancy; when, recurring incessantly to pretended contrasts between the two worlds, it was imagined that the whole of Africa and of America resembled the deserts of Egypt and the marshes of Cayenne. At present, when men judge of the state of things, not from one type arbitrarily chosen, but from positive knowledge, it is ascertained that the two continents, in their immense extent, contain countries that are altogether analogous, and that there are regions of America as barren and burning as the interior of Africa."[2] It is indeed true that the migration and distribution of organized bodies can no more be solved as a problem in physical science than the mystery of their original creation; and that "the task of the philosopher is fulfilled when he has indicated the laws in accordance with which nature has distributed the forms of animal and vegetable life."[3]

Geographical Distribution.

In regard to those exquisite tribes which form the more immediate subjects of our present observations, it is known that the increasing intensity and continuance of heat exert a powerful influence on the size, structure, and external adornment of the species. The nearer, in general, that we advance towards equinoctial countries, the more remarkable do we find these creatures, for their largeness of dimension, their singularity of form, and their depth as well as splendour of colour. An accurate knowledge of the distribution of insects is of the highest interest to the geologist and geographer as well as to the entomologist, and may be the means of determining, in doubtful or disputed cases, the natural and what may be called the original limits of countries; as, for example, in the case of islands situated at nearly equal distances between two distant continents. But we cannot here pursue the subject under a more extended form.[4]

Having thus cursorily considered the geographical distribution of insects, we may now devote a brief space to their *local* distribution, or favourite haunts, according to their kind, in any given district. The surface of a country, it has been observed, consists either of mountains, hills, and valleys, or of plains. In either case it may be bare and exposed, or diversified by forests, groves, or copses; and it may also be dry and sandy, or rich and well watered by lakes and rivers. Such parts as are uncovered are greatly varied by the hand both of art and nature, and present heaths or grassy downs, marshes, meadows, or tillage land, each of which is characterized by a difference of soil as well as of vegetable surface. In each the careful entomologist will discover peculiar kinds of insects. "As mountains and hills have usually their own Flora, the insects appropriated to alpine plants can only be met with where their pabulum is found. Here also those northern insects that are impatient of a warm climate will take their station if they migrate to the southward. The predacious beetles likewise sometimes frequent a mountainous district. *Carabus glabratus* was first taken by Professor Hooker on Ingleborough; and probably, if the Welsh and Scotch mountains were duly investigated by an entomologist, many novelties would reward his toils. The valleys and plains, especially those of a sunny exposition, abound in insects. When the heat of the atmosphere indisposes you for motion, you will find it no unprofitable or unpleasant employment, lying on the grass, to search for minute beetles, which you will there find coursing about amongst the tufts and roots of the herbage. Thus you may procure many of the *Pselaphidæ*, which you would not otherwise meet with. Even when the grass is grown up, insects are fond of alighting upon

Annales du Muséum, t. ii. p. 35; and *Thoughts on the Geographical Distribution of Insects*, in the 6th No. of the *Entomological Magazine*.

Geographical Distribution.

its spikes, and thence drop or run to the ground. Should circumstances ever carry you abroad to the steppes or grassy plains of Tartary, or to Hungary, you will find there two or three species of the singular genus *Lethrus*, which burrows in the soil. Every hole is inhabited by a male and female;—from it they issue to attack the plants or vines; and having cut out the heart of a plant, go backwards like a crab with the prize to their burrow. At the time of pairing, sometimes violent battles, encouraged by the female, take place between the male and a stranger of that sex desirous of admission, which cease only with the death or flight of the stranger. The vicinity and borders of *woods* generally abound in insects of every order, and, if you proceed as hereafter directed, will furnish you with numerous prizes, especially of Lepidoptera. Here alone you can meet with the purple emperor butterfly (*Apatura Iris*); and if properly equipped you may readily secure him."[1]

The aquatic beetles of the genera *Dytiscus*, *Colymbetes*, &c. of course occur in the water. During the evening twilight, however, they frequently leave their moist abodes, and wing their way over the adjacent country. When surprised, after their nocturnal adventures, by the rising sun, they will plunge into whatever water is nearest at hand, and thus rain barrels and washing tubs are sometimes not looked into in vain. Chance often throws into the hands of an entomologist what he has long sedulously sought for without success; and an open window and a lighted candle will sometimes procure what a traverse through the forest, worthy of a North American Indian, would not have obtained. By collecting aquatic plants, duckweed, and "the green mantle of the stagnant pool," and afterwards examining these productions at leisure in a basin of water, many valuable insects of the minuter kinds may be procured. Although the *Gyrinus Viola aquatica* is said to inhabit salt water, that element may be regarded as decidedly adverse to insect life. Brackish water, however, produces several peculiar species, such as *Hydræna marina*, and the large-eyed Cimicidæ. According to Latreille, the genus Pimelia occurs only in soils impregnated with saline particles, or where the genus *Salsola* abounds.

Heaths, though in a general view unproductive of insect life, yield some very beautiful species, such as *Carabus nitens* and *arvensis*, and *Cicindela sylvatica*. In regard to *soils*, such as are light, according to Mr Kirby, are most prolific in insects. Warm sandy banks are frequented by *Cicindela campestris*, *Opatrum sabulosum*, *Helops quisquilius*, &c.; and chalk is extremely attractive. The *Licini*, *Papilio Cleopatra*, several species of *Dasytes*, and *Lamiæ*, seem to delight in the latter substance. Many others are found in chalk-pits, which Mr Kirby does not think should be regarded actually as chalk insects; but rather that they simply fall into the pits, and then become more discernible in consequence of the stronger contrast of colour. By watching in one of these pits during a warm day, vast numbers of insects may be taken. Of all soils *clay* offers the fewest inducements to the entomologist.[2]

Old trees, felled timber, and planks which have lain long upon the ground, should be carefully examined by the collector, as on the under sides of the latter, as well as beneath stones, many species seek repose and shelter. Thorn and other fences, whether dead or living, are very productive; and gates, posts, and wooden rails, ought in nowise to be neglected. Although the *sea* itself, according to the authority last quoted, produces no true insects, yet many and varied tribes are known to haunt its shores. On the sand hills of the Norfolk coast Mr Kirby found *Ægialia globosa* and *Cicindela hybrida*. *Rynchænus horridus* likewise inhabits thistles growing near the sea. Fuci and other marine rejectamenta, which border the margins of friths and estuaries, produce peculiar species of *Cercyon*, some *Aphodii*, and many *Staphylinidæ*. That singular insect *Oxytelus tricornis* has been captured in a situation like that now indicated. The inundations of rivers in spring, summer, and autumn, sweep innumerable insects from their hiding places; and when the waters begin to subside, the examination of the floating grasses, broken twigs, and various debris which line the indented shores, will afford an ample field for the investigations of the entomologist. To him indeed the most barren scene, whether of dreary moor or desolate mountain, can never be devoid of interest,—for the more untrodden the path the stronger and more rational are his hopes of becoming possessed of some of those treasures which are everywhere scattered over the wilderness of nature,—hitherto unperceived perhaps by human eye, but nevertheless performing an essential part in the great and solemn mystery of creation.

The geological relations of insects do not appear to have attracted the notice of naturalists,—we mean their more direct connection with rocks, independent of that intermediate relationship which results from the dependence of particular plants on certain soils, and the known alliance of many tribes of insects with peculiar forms of vegetable life. Mr Wailes always found the larvæ of *Enicoceri* on rough slimy stones, and he found it as great a waste of time to look for them on a smooth limestone, as to turn up a fragment of basaltic rock (whinstone) in search of geodephagous insects. The repugnance of beetles to basalt he had previously noticed. The subjacent rock of the wild district of Teesdale is almost exclusively composed of the basalt of the great whin-sill, the formation of which is regarded as a knotty point by geologists. Of course the loose and superficial stones of the country are its fragments, and among these scarcely a beetle is to be found, except a few which are superlatively common elsewhere, though *inter rariores* in the district referred to. "So far," says Mr Wailes, "as my observations, whether confined to single stones, or extended over a whole district, go, any place having limestone, particularly the magnesian, for its subjacent stratum, will afford abundance of the *Geodephaga*, as well as most other Coleoptera, whilst they will be found very thinly scattered over a basaltic region. It is strange to notice the almost uniform absence of these insects on turning up a whin which has accidentally found its way into a heap of other stones, though every one of the latter may have one or more tenants under it. Must we not look to the comparative dryness of the limestone and humidity of the whin for an explanation? We can readily account for the great predominance of the land *testacea* on a limestone district; but lime does not enter into the composition of beetles."[3]

Insects may also be viewed in relation to their seasons of appearance, or the most appropriate periods for the collection of the different kinds. Such as gather honey and the pollen of plants are among the first to proclaim the approach of spring; and their appearance may be dated from the blossoming of certain trees and flowers of common occurrence. Other plants, likewise accompanied by peculiar insects, blossom later; and thus we may trace a mutual relationship between the two kingdoms throughout the sparkling spring, the leafy summer, and the melancholy autumn,—till relentless winter sets his seal upon insect life, and either renders it entirely torpid, or sheds occasionally a feeble ray on some forlorn company of gnats, whose dances, now no longer "choral," exhibit but a sad representative of that more genial season when the "living air" was filled with their not unjoyful murmurs. With these and a few other exceptions, the earliest insect season commences with the flowering of the sallow (*Salix caprea* of Linnæus, *Saugh* of the Scottish schoolboy), which is accompanied by the golden flowers of the crocus, and the beautiful green of the expanding gooseberries. "Then is your time," says Mr Kirby, "to collect many species of wild bees and *Diptera*, not afterwards to be met with; and various other insects now begin to emerge from the pupa. Another and later season is marked by the general blossoming of the buttercup (*Ranunculus bulbosus*), accompanied by the marsh-marygold (*Caltha palustris*), and ladies' smock (*Cardamine pratensis*), when you may hunt the pastures, meadows, and marshes with success, and take some insects that do not show themselves later. The coprophagous insects are now abundant. Amongst others, *Aphodius testudinarius*, a perfectly *vernal* species, is now only to be taken, and usually flying. A *third* insect season indicated by Flora, and a very prolific one, commences with the blossoming of the hawthorn, when you must desert the meads for the inclosures. At this time all nature begins to put on her gayest attire, and all her insect tribes are now on the alert, and fill the air. They are almost universally attracted by the sweet and lovely blossoms of the plant just named; so that, by examining them, you may entrap some of every order, and many that during the year will appear no more. Even many of the saprophagous insects will sip nectar from the flowers. The umbelliferous plants proclaim the fourth season of insects, particularly the wild carrot and parsnip. You will scarcely ever fail to find, if the weather is genial, *hymenopterous* and *dipterous* insects of various genera, especially such as have a *short* tongue, engaged in collecting the honey from those plants. Here you may take some of the rarer *Chrysidæ*, *Crabronidæ*, *Cercerides*, &c. and occasionally even *Coleoptera*. The last insect season may be dated from the general flowering of the thistle tribe. When these are in blossom is the best time of all to collect the humble-bees (*Bombus*), the leaf-cutter bees (*Megachile*), and many other *Apiariæ*, Lat. which alone, by their long tongues, can imbibe the honey and collect the pollen of these flowers. The male humble-bees frequent them to the last, and often seem as if they were intoxicated with their sweets."[1]

The preceding chapters contain whatever we have to say of a general nature regarding the CLASS of insects. We shall now proceed to the particular history of those primary divisions called *Orders*, the name and nature of each of which have been already briefly expounded at the commencement of this article.

ORDER I.—COLEOPTERA.[2]

Coleopterous insects have usually four wings, the two superior of which, called elytra, resemble horizontal, somewhat convex scales, which meet in a straight line along their inner margins, where they form what is called the dorsal suture. The inferior wings, which are the true organs of flight, are membranaceous, transparent, transversely folded, and covered and protected by the elytra or wing-cases. They are all masticating insects, provided with mandibles and maxillæ.

Of all the insect tribes these are the most numerous, the best known, and the most generally interesting. Their singular and varied forms, their brilliant colouring, the great size of many species, and that solid consistence which renders their collection and preservation comparatively easy, have long secured for them the devoted attention of the entomologist. Some advantages also result to their study and classification from the clearly defined and articulate forms of their external organs. The name and principal characters of the order were bestowed and defined by Aristotle, and have been adopted by almost all succeeding writers on the subject. Other characters have no doubt been added to his ancient definition of *wings in a sheath*,—such as the transverse folding of these organs, and the straightness of the suture by which the elytra are united; and several exceptions to the supposed universal attributes of the order have been discovered,—such as the female glow-worm, which has neither wings nor sheaths, and the genus *Meloe*, and many *Carabi*, which, though furnished with sheaths or elytra, are entirely destitute of true or membranaceous wings. So also, in the genera *Buprestis*, *Molorchus*, and others, we may discover exceptions to the transverse folding of the last-named organs; and the exact fitting or junction of the elytra, forming the dorsal suture, ceases to hold in the genus *Meloe*,—so that none of these characters can be regarded as universal; but as they are very generally prevalent, and a few exceptions do not invalidate a rule, it is advisable that they should be retained for the purposes of definition.

Coleopterous insects, like others, are composed of three principal portions, head, thorax, and abdomen. The *head* varies greatly both in size and form, according to the different tribes. In the great section of the *Geodephaga*, or ground-beetles, it is usually of a somewhat triangular form; in many of the short elytra'd tribes (*Brachelytra*) it is orbicular; while among the weevils (*Curculionides*) it is prolonged into a pointed rostrum or beak. The hinder part is frequently contracted into a short neck, and is inserted into a cavity of the thorax, in which it moves as in a socket. The head bears two *antennæ*, of which the form and structure differ not only in the different genera, but even in the sexes of the same species. They usually, however, consist of ten or eleven distinct articulations, the latter number being the more frequent. They are inserted in the front of the head, anterior to, and rather beneath, the region of the eyes. Their various forms, as characteristic of particular groups, will be afterwards described. The *eyes* of Coleoptera, in the perfect state, are two in number, and composite. In certain Staphylinidæ, two small yellowish points have been observed, which some naturalists have regarded as analogous to the simple or stemmatic eyes; but the sentiments of Latreille are adverse to that opinion. The actual eyes are either entire, notched, or even occasionally so completely intersected by a little corneous stalk, as to exhibit (as in the genus *Gyrinus*) the appearance of a pair on either side. The *mouth* consists of a *labrum*, two *mandibles*, two *maxillæ*, each furnished with one or two articulated *palpi*, and a

---

[1] *Introduc. to Ent.* vol. iv. p. 508.

[2] The derivation or etymology of the different orders has already been given in our introductory observations,—see pages 59 and 60 of this volume. Our present order corresponds to the ELEUTHERATA of Fabricius.

labium composed of two parts, the *mentum* and *ligula*, and accompanied by a pair of palpi. The mandibles are usually of a corneous consistence, but they are membranaceous and of small size, in such as take little apparent nourishment, or feed on the juices of flowers, or on excrementitial or putrescent animal fluids. The maxillæ are of a softer texture than the mandibles. When there are a pair of palpi on each maxilla, the exterior ones never consist of more than four joints; those of the labium have usually three articulations.

The *thorax* of the Coleoptera, like that of other hexapod insects, is likewise divisible into three principal portions, each of which is characterized by a particular degree of development. The *mesothorax* is very narrow, whilst the corselet or *prothorax*, and the *metathorax*, exhibit a considerable bulk. This is an important feature in the structure of the skeleton or tegument of the coleopterous order. The prothorax is always free in its movements, while the two other portions are united together, and nearly immoveable. The component parts of the mesothorax are in fact rudimentary, and those of the *scutellum* are soldered together. But the elements of the latter portion, that is, the *præscutum*, the *scutum*, the *scutellum*, commonly so called, and the *postscutellum*, still exist, and their joinings are quite perceptible in certain genera. The prothorax supports only the first pair of legs, while the mesothorax bears the second pair and the elytra. The second pair of wings and the third pair of legs are attached to the metathorax.

The elytra and wings take their origin from the lateral and superior margins of that portion of the body to which they are attached. The elytra are usually of a very firm or almost crustaceous consistence, opake, and without reticulations. The true wings are large, veined, and concealed beneath the elytra. The latter always exist (with the exception of the females of a few species), but many species are apterous, so far as concerns the existence of the membranaceous wings. In general the elytra equal the body in length, but they are sometimes, as among the Staphylinidæ, much shorter. They are usually free, and extended during the act of flight; but among several carabideous insects they seem united by the dorsal suture, and are consequently incapable of extension. In these instances the true wings are wanting.

The *abdomen* of the Coleoptera is sessile, that is, attached to the metathorax by its largest transverse diameter. Its inferior or ventral part is less extended longitudinally than the superior, and this restriction is chiefly owing to the development of the sternum of the metathorax, which is prolonged backwards, and thus, as it were, usurps the place of the abdomen. This may be very distinctly observed in the genus *Copris*, in which the segments of the abdomen seem crowded together. In some species the first segment appears divided into two parts by the sternum, which projects along their line of union. Inferiorly, the abdomen is always of a firm or horny consistence; but the upper part is generally soft, being covered by the elytra and wings. When these are wanting or abbreviated, the abdomen is equally hard above as below, as in the genus *Meloe*, and the *Staphylinidæ*, or brachelytrous tribes.

The legs vary in their structure and development. The anterior pair, or those of the prothorax, are frequently more strongly formed in the male than in the female; and in the former sex the tarsi are often broader than in the latter. The legs are usually described as composed of five pieces, the *haunch*, the *trochanter*, the *thigh*, the *tibia*, and the *tarsus*. M. Audouin has shown the existence of a sixth portion, moveable, constantly concealed within the interior of the body, and serving to articulate the haunch with the epimera. We have already mentioned it under the name of *trochantin*.

The internal structure of the Coleoptera has recently been illustrated by several ingenious observers, such as Ramdhor, Audouin, and Dufour.

The apparatus for the purposes of nutrition in coleopterous insects may be summed up as follows:[1] 1*st*, Organs of manducation; 2*d*, salivary glands; 3*d*, a digestive tube; 4*th*, biliary vessels. The entire order Coleoptera is composed of *masticating* species, which are consequently provided with instruments of a more or less resistant nature, adapted for seizing, cutting, and triturating the food previous to its being swallowed. For this purpose the mouth is furnished with a pair of corneous mandibles, sometimes simply incisive, sometimes dentated or toothed. Their motion is transverse and horizontal. There is also a pair of maxillæ, usually of a more membranaceous consistence than the mandibles, an upper lip or labrum, an under lip or labium, and from four to six palpi. The salivary glands, which in orthopterous and hemipterous insects present all the characters common to such organs, are rudimentary in size, and few in number, among the coleopterous tribes. They contain a colourless saliva, and their existence hitherto has been ascertained chiefly in genera of the families of *Melasoma*, *Taxicornes*, *Stenelytra*, *Trachelides*, *Rhincophora*, and *Aphidiphaga*. The digestive tube possesses an extent which varies singularly in relation to the habits of life of each particular tribe. In a few it scarcely exceeds the length of the body; while in others, and these are the greater number, it greatly surpasses that extent. The œsophagus is generally short; the crop more or less obvious; the gizzard is in some families garnished interiorly with triturating pieces; the chylific ventricle is of variable size, and either smooth or beset by papillæ; the small intestine likewise varies in length; the large intestine consists most frequently of a dilatable cæcum; the rectum is sometimes greatly elongated in the female sex.

The texture of the digestive tube is musculo-membranous, and is composed of three tunics of varying thickness. The biliary or hepatic vessels are always inserted at the posterior extremity of the chylific ventricle. They are of great extent, extremely slender, singularly folded, and of a cellular-membranous texture. Their number and the mode of their connection vary in the different tribes and genera, but they are always of an equal number, or in pairs. There are never less than a single pair, nor more than three. Sometimes their insertion is limited to the chylific ventricle, in which case they are either free and floating by one extremity, or they form an arch variously twisted, of which the two extremities are implanted on the same circle. Sometimes the insertion is double, and obtains at one end on the chylific ventricle, and at the other on the cæcum. The bile contained in these vessels varies from a deep violet and brown colour, to yellow and white. It is sometimes even diaphanous.

The generative system among the Coleoptera is thus described by M. Dufour. "Les Coléoptères ont, ainsi que les autres insectes, deux sexes séparés, et l'acte de la reproduction est un véritable accouplement. L'organe générateur mâle se compose, 1°. de deux testicules formés, soit par les replis agglomérés d'un seul vaisseau sper-

---

Coleoptera.

matique, soit par un ou plusieurs sachets, soit enfin par des utricules dont le nombre, la configuration, et la grandeur varient suivant les familles ; 2°. de deux canaux déférens variables pour leur longeur, quelquefois reployés en épidedyme ; 3°. de vésicules séminales plus ou moins nombreuses, et de formes diverses suivant les genrcs de Coléoptères ; 4°. d'un conduit éjaculateur tantôt fort long, tantôt très-court ; 5°. d'une verge retractile renfermée dans une armure copulatrice dont la conformation se modifie à l'infini. On distingue dans l'organe générateur femelle de tous les Coléoptères, 6°. deux ovaires dont chacun se compose d'un calice plus ou moins marqué, et d'un nombre variable suivant les genres, de gaines ovigères uniloculaires ou multiloculaires, terminées le plus souvent par une pièce charnue où se fixe un ligament suspenseur ; 7°. un glande sébacée d'une structure diversement compliquée, insérée à l'origine de l'oviducte, et destinée à furnir une humeur propre à lubrefier ou à enduire les œufs à l'époque de la ponte ; 8°. un oviducte plus ou moins long qui se continue en un vagin ; 9°. enfin, dans quelques cas rares un appareil sécréteur particulier propre à former une enveloppe commune ou une coque aux œufs."[1]

Besides the ordinary secreting organs, certain coleopterous species are provided with a kind of excrementary secreting apparatus, which is binary, and common to both sexes. Its function is the formation of an acrid humour, liquid or gaseous, which the insect expels as a means of defence when menaced or attacked.

The respiratory organs of the Coleoptera consist in stigmata placed along the lateral portions of the body, and of tracheæ, sometimes tubular, sometimes utricular, which disseminate the air through all parts of the system.

The nervous system is composed of a brain or upper ganglion,—of ganglia placed in the median line, variable in their number, and communicating with each other and with the brain by means of a double cord,—and of nerves, properly so called, which emanate from the ganglia.

The abdominal cavity of these insects always encloses a splanchnic adipose tissue, of which the abundance and colour vary according to the genera, and which appears to be connected with the purposes of nutrition.[2]

In addition to the usual differences, the sexes frequently present external distinctive characters in the antennæ and other parts. The male is supposed to perish soon after the sexual union, and the female does not long survive the deposition of her eggs. These eggs, which of course vary in size, form, colour, and consistence, are deposited in various localities, and among very different substances, in accordance with the instincts and economy of the species, and the habits of the larvæ about to be produced. These larvæ are also very dissimilar to each other in this varied order; but they may be generally described as soft bodied, with the exception of the head and the upper portion of the three first segments of the body, which are of a firmer or more scaly consistence. They are furnished with six feet; and the eyes, which in the perfect state are composite, are in this early condition small granuliform bodies, sometimes amounting to six on each side. The parts of the mouth bear a relation, both to their immediate mode of life, and their future development in the perfect insect. The mandibles are very strong and corneous in such species as feed on ligneous substances; they are coriaceous in such as feed on leaves, and almost membranaceous in those which prefer carcasses, or other matters in a state of putrescence. The antennæ of these larvæ are usually very short, cylindrical or conical, and composed of a small number of articulations.

Coleopterous insects enjoy a considerable length of life, at least in the larva state. The period of endurance, however, of that early condition, is extremely various in the different genera of this most numerous order. Indeed, even among individuals of the same species, the continuance of the different stages of growth varies in accordance with the temperature of particular seasons, or the more or less abundant supply of food. Many species pass the winter in a listless state, abstaining almost entirely from eating, and consequently, even after the lapse of several months, present scarcely any apparent increase of their dimensions. No sooner, however, are they awakened from their temporary trance by the enlivening beams of the returning sun, than they greedily attack their favourite food, and their growth is almost instantaneous. It has been remarked that the larvæ which feed on leaves, such as those of *Crioceris*, *Altica*, and *Chrysomela*, remain but a brief period in the larva state; while the subterranean and root-devouring species, on the contrary, not unfrequently continue for two or three years in their dark abodes. Attentive observation has also ascertained that those Coleoptera which pass the winter in the egg state are the shortest lived in the form of larvæ;—they are hatched, nourished, developed, reproduce, and perish, all in the course of the summer first ensuing,—while such as pass the winter in the larva state, or that of nymph, are the longest lived in both of those conditions. It is chiefly in the form of larva that the Coleoptera produce such injury to agriculture, and other branches of rural industry. The ravages of species belonging to the genera *Bruchus*, *Curculio*, *Calandra*, *Melolontha*, *Crioceris*, *Altica*, *Anthrenus*, *Dermestes*, and numerous others, are unfortunately better known than any counteracting remedies of easy application.

The larvæ of the coleopterous tribes usually change their skins three times, and many of those which live in the earth construct a kind of cocoon, in which they undergo their transformations. These are of the kind formerly mentioned under the name of *complete* metamorphoses.

Linnæus, Geoffroy, Fabricius, Olivier, Latreille, and others, have established many divisions, more or less natural, in the coleopterous order. The number of the articulations of the tarsi varies from three to five, and their amount in each limb has been assumed as the basis of the great sectional divisions of the coleopterous order, so generally adopted by the continental naturalists. As these divisions pervade all foreign works of importance on the Coleoptera, we shall here explain their nature. Geoffroy having observed that all the species of a genus or of a family were characterized by the same number of articulations of the tarsi, and that the differences presented by these parts always bore a relation to other differences in the general organization, he conceived the idea of grounding his primary divisions on their particular structure.

Many extensive families of coleopterous insects are distinguished by *five* articulations to the tarsi; that is, by five joints on each foot. (See Plate CCXX. fig. 2 *e*.) All of these fall under the first general section called *Pentamera*, from πεντα, *five*, and μερος, *part* or *article*. Another extensive division is characterized by *five* articulations to the tarsi of the two anterior pair of feet, while the posterior or third pair possesses only *four* articulations. All the species so formed belong to the section *Heteromera*, so called from ἑτερος, *different*, the tarsi being dissimilar to each other. Numerous Coleoptera exhibit the tarsi composed throughout of four articulations. These are ranged under the general section *Tetramera*, from τετρα, *four*. Lastly, many species have no more than three, and some no more than two joints, to the tarsi, and these belong respectively to the sections *Trimera* and *Dimera*. It has even been supposed that an insect exists, the tarsi of which are furnished with only a single joint; and for its reception the section *Monomera* (from μονος, *alone*) has been established. Later and more considerate observation, however, has led to the belief that both of the last-named sections are resolvable among the trimerous species, and that the supposed absence of the second and third joints arises from their extreme minuteness.

---

[1] *Ann. des Sciences Nat.* t. viii. p. 38.

[2] *Ibid.* p. 40.

"Nihil notatu dignius videtur," observes Mr Fischer, "constanti tarsorum insectorum imprimis coleopterorum formatione, quæ, quidquid etiam naturæ scrutatores, quidam contra eam in medium protulerint, methodum ordines insectorum in sectiones vel series minores dirimendi offert tutissimam."[1] The extreme simplicity, and consequent ease of application, of the sectional rules deduced from the structure of the tarsi, has probably induced the continental naturalists to adopt them more readily than they would have done had they foreseen the occasional contradictions to which they lead. The fact cannot be disguised that the system is in many instances artificial,—for several insects differ in the number of their tarsi, which are yet nearly allied by their general structure and attributes,—while it would be easy to show that the mere agreement in the number of those parts by no means carries along with it a corresponding relationship in the form of the other more important organs.[2] The truth is, that the articulations of the tarsi differ in some instances even in the sexes of the same species, as may be seen in *Cryptophagus fumatus* and *C. pallens*; and the consequence, as Mr Macleay has pointed out, of forming the primary divisions in accordance with their amount, has been, that many genera are separated, and thrown to a great distance from the place which nature has assigned them.[3]

While, therefore, the British naturalists have availed themselves of whatever aid these sectional divisions have legitimately afforded, they do not trammel themselves by a uniform adherence to the system, independent of its accordance with nature.[4]

We have already endeavoured, in the preceding introduction, to illustrate the geographical distribution of insects in general. We shall here add a few observations more especially applicable to the coleopterous tribes.

The coleopterous insects of Europe in general, according to M. Latreille, bear a strong affinity to those of Western Asia and Northern Africa. These traits of resemblance become more obvious, when, the qualities of the soil and the temperature being analogous, we approach towards the northern tropic. It is under the forty-fourth degree of north latitude that we begin to perceive certain species of carnivorous Coleoptera, of the Lamellicornes, of the heteromerous section, and of the Curculionides, characteristic of the warmer regions of the earth. There also may be observed species of a larger size, and of an aspect more imposing, than characterize their congeners of the north. The dominion of the *Carabi*, properly so called, so notable over all the northern and temperate countries of Europe, and in the more western regions of Asia, ceases towards the thirty-fifth degree of north latitude. These predaceous insects are succeeded by the genera *Anthia* and *Graphipterus*. Viewed in relation to entomological characters, Europe may be said to extend further eastward than it does in accordance with our actual political divisions, as the insects of the Levant, and even of Persia, exhibit a very European aspect. Austria and Hungary, from their central situation and other local circumstances, are numerically richer in species than the western countries of Europe. These latter, however, possess, in consequence probably of their littoral position, and the influence of the oceanic waters, several peculiar species, which, though unknown in the East, nevertheless extend their localities in a lengthened line from north to south. However gorgeous may be the productions of tropical regions, the European continent presents to the entomologist a rich and varied assemblage both of carnivorous and herbivorous Coleoptera. Many of these it possesses in common with other countries, while of some it has to boast a more exclusive possession. The great tribe of the Carnivora, and especially the Carabi or larger predaceous beetles—the *Staphylinidæ* or brachelytrous kinds—the *Clavicornes*—the genera *Aphodius*, *Meloe*, *Callidium*, *Leptura*, *Chrysomela*,[5] *Lixus*, &c.—are there proportionally more numerous than in any other quarter of the world. Latreille has observed that the herbivorous Coleoptera seem to prevail in South America. Many species of the northern countries of the new world greatly resemble those of the northern and temperate parts of Europe, while others are identical. Of these some may be regarded as naturally distributed alike over Scandinavia, Greenland, the adjacent islands, and North America,—while the greater proportion, which are xylophagous or timber-eating insects, have very probably been transported by artificial means, that is, in cargoes of wood, and in the timbers of our vessels. Notwithstanding many examples which might be adduced to illustrate a certain agreement which exists between the species of Europe and North America, the more general as well as precise truth is, that the entomology of North America is connected by a stronger affinity with that of the southern division of the new world than with that of our own continent and islands. We cannot, for instance, exhibit a single example of that division of *Cetonia* of which the thorax presents a posterior lobe, nor of *Galerita*, *Tetraonyx*, or *Parandra*, genera which are distributed throughout the whole of America. One strong feature of conformity has indeed been observed, that North America and Europe both possess many carnivorous Coleoptera entirely unknown in the equatorial regions either of the old world or the new.[6]

The coleopterous order is extremely numerous in species. Comte Dejean's collection, probably the most extensive hitherto made, is said to contain above twenty thousand different kinds; and Mr Stephens' *Nomenclature of British Insects* (second edition) presents us with the names of 3614 indigenous Coleoptera.

[1] *Genera Insectorum*, Præf. p. 5.

[2] "Ce n'est pas assez," says Clairville, "pour pallier les frequentes anomalies qui se rencontrent, de dire que tel insecte a cinq articles aux tarses quoiqu'on n'en découvre que quatre. Il devroit en effet en avoir cinq d'après la règle qu'on a établie. Cependant ces explications, toutes ingenieuses qu'elles sont, ne peuvent me convaincre, et je ne puis me détérminer a supposé plus d'articles aux tarses qu'on ne peut réellement en decouvrir, en y mettant toute l'attention possible. Le nombre des articles doit être clair, positif, et uniforme, sans quoi le charactère est vacillant. Au reste, je ne disconviendrai pas que sans être rigoureusement propres à diviser les ordres, ils ne puissent tres-bien servir pour un tableau dans lequel les genres seroient ordonnés selon le nombre des articles des tarses." (*Entomologie Helvétique*, p. 30.)

[4] *Entomologia Edinensis*, Introduc. p. 23.

[5] M. Lacordaire, however, has recently shown that the *Chrysomelidæ* are very numerous in the tropical regions of South America. See *Nouvelles Annales des Mus.* t. ii. p. 94.

[6] *Introduction à la Géographie générale des Arachnides et des Inscctes, ou des climats propres à ces Animaux.* Par Latreille.

In relation to the economical uses of the order, we may observe that coleopterous insects are scarcely if at all applied in the arts. Those employed in medicine are chiefly the *Cantharis vesicatoria*, commonly called the Spanish Fly, and the *Mylabris Cichorii*, which in China and the Levant is likewise used as a blistering application. The Romans are supposed to have made use of certain coleopterous larvæ for dietetical purposes; and some of the South American tribes are known to devour with delight the fattened larvæ of the *Curculio palmarum*. We shall conclude these introductory observations by a few remarks

On the collecting and preserving of Coleopterous Insects.

This is a very simple matter to those who are zealous in the cause. By far the best method is for the collector to provide himself with a few stout phials half filled with whisky, or any other ardent spirit which he may happen to prefer. When the insects are caught, which they can only be in any considerable number or variety by a sedulous search under stones, and in the other localities afterwards indicated in our notices of the different genera, they may be popped into the phial, where in most instances they die almost instantaneously. This is not only the most humane process, but it is also the best mode of preserving their more delicate portions uninjured. It likewise puts an end to all contention among themselves, which is by no means the effect of the ordinary method of collecting in small boxes,—for in the latter case the larger and more voracious invariably devour the smaller or least assuming; and thus many captures, regarded with pleasure in the morning, are found to have disappeared in the afternoon. If time and opportunity are wanting for the immediate purpose of *setting* the specimens, that is, placing them in their most appropriate positions, they may be allowed to remain in the phials for days or weeks without being injured, although in that case greater care is afterwards necessary, especially with the smaller specimens, in consequence of a certain softness in the articulations, induced by maceration in the spirits. When an entomologist (in search of Coleoptera) is employed in what we may call the *home circuit*, he requires during his excursions nothing more than a couple of glass phials, as we must suppose him possessed of all other appliances within his dwelling. But during a more distant and prolonged journey, he must provide himself with a few small boxes made either of wood or tin (the last is lighter and thinner, and therefore more commodious), lined with cork at top and bottom, and deep enough to contain an upper and an under range of pins. In these the insects caught during the day may be transfixed in the course of the evening, so that the phials may be left empty for the captures of the ensuing morn. Notes ought to be taken of the places of capture, and the insects should be so arranged in the boxes that, by means of numerals or other marks, any individual may be afterwards recognised in relation to its own particular locality.

The *setting* of an insect consists merely in placing its limbs and antennæ in a natural position, and fixing them in the same for a time by means of pins, on a small board on which there is a layer of cork. (See Plate CCXX. figs. 10 and 12.) They stiffen in a few days, and may then be transferred to their proper places in the cabinet. If not set when either moist or recent, they may be softened by being placed for a night in any small vessel containing a layer of wet sand, and covered with a damp cloth to prevent evaporation. The same process, continued for a somewhat longer time, is equally efficient in regard to foreign species. Each specimen, if not stuck, should, previous to setting, be transfixed by passing a pin through the elytra and abdomen, at right angles with the plane of its position,—enough of the pin being made to project beyond the feet as will suffice to fix its point firmly in the cork.

When mould appears upon coleopterous specimens, they ought to be exposed for some hours at the distance of two or three feet from a brisk fire, and then delicately brushed with a hair pencil. When mites or acari make their appearance among them, they ought either to be exposed for a few minutes to a high temperature, which kills the living parasites without injuring the dead insects, or each specimen ought to be carefully washed by means of a hair pencil dipped in spirit of turpentine. A piece of sponge constantly saturated with that fluid, or a supply of camphor, should be kept in each drawer. With a view to maintain a collection in good order, it is very advisable that all specimens obtained from correspondents by purchase or exchange should, previous to their being placed in the cabinet, be submitted to the ordeal of a bath either in spirit of turpentine or camphorated spirit of wine. If mites or acari are once introduced into a cabinet of considerable extent, their eradication is extremely troublesome. As many collectors are careless of their duplicate specimens, and as it is of course with these that they supply their friends, much injury is frequently inflicted by the introduction even of a single insect in bad condition into a cabinet previously in a proper state.[1] We must now proceed to a more detailed exposition of the coleopterous tribes. They are grouped together under four great sections, according to the number of joints in the tarsi.

PENTAMERA.

All the Tarsi composed of Five Joints.[2]

FAMILY I.—CARNIVORA, Cuv. ADEPHAGA,[3] Clairv.

The first primary division of the coleopterous order contains a numerous and varied assemblage, all of which, however, agree in being, as the name imports, of a voracious disposition. Each maxilla is furnished with two palpi, so that there are *six* in all, including those of the labium.

In the larva state, these insects are elongated, cylindrical, composed of twelve rings or segments, exclusive of the head, which is large, of a scaly texture, and provided with two strong mandibles curved at their extremities. The mouth is also furnished with a pair of maxillæ divided into two branches, one of which is formed by a palpus. The ligula bears two palpi, which are shorter than those of the maxillæ. The head is moreover provided with a pair of short conical antennæ, and six small simple

---

[1] *Entomologia Edinensis*, Introduction, p. 57.

[2] We have already stated our opinion of the artificial combinations which occasionally result from the use of this principle of sectional division, and in our *Entomologia Edinensis* we have, with our coadjutor, the Rev. James Duncan, followed another mode of arrangement. But in presenting a general view of the subject, and one in which numerous foreign genera are included, we think that greater clearness will result from an adherence to the system of the continental entomologists. We therefore now follow M. Latreille.

[3] So named from αδηφαγος, voracious.

Coleoptera Pentamera.

eyes on each side.[1] The first segment of the body is covered by a squamous shield,—the others are soft. The first three segments are each furnished with a pair of legs, of which the extremity is curved forwards.

Of course many modifications occur in the form and aspect of adephagous larvæ. For example, those of the Cicindelæ have the upper portion of the head hollowed out in the centre, while the inferior portion is bulged. Two of the eyes on each side are much larger than the others, and the shield of the first segment of the body is also large, and of a semicircular shape. The eighth segment bears two small hooked processes in its upper surface. Among the generality, however, of these larvæ, the head is weaker and more regular, and the eyes are of equal size. The shield is square, and does not project over the sides; the eighth segment wants the processes; but the terminal segment is furnished with two conical appendages, besides a membranous tube formed by the prolongation of the anal portion of the body. These appendages are toothed and horny in the larvæ of *Calasoma* and *Carabus*. In *Harpalus* and *Licinus* they are more elongated, fleshy, and articulated. In these and other genera, the form of the mandibles in the larvæ approaches that of the same species in the perfect state.

The adephagous Coleoptera have always a first stomach, which is short and fleshy,—a second, which is more elongated, and shaggy on the surface, by reason of the numerous small vessels with which it is furnished,—and a short and slender intestine. The hepatic vessels, four in number, are inserted near the pylorus. These insects may be regarded as terrestrial (*Geodephaga*) and aquatic (*Hygrodephaga*), according to their mode of life.

The genera of the former subdivision of the order dwell and take their food upon the surface of the earth. They are hence known under the name of ground-beetles. The feet of these *terrestrial* species are formed for tolerably rapid motion, and the two posterior pair are inserted at equal distances. The mandibles are obvious and discovered, the terminal portion of the maxillæ is straight inferiorly, and curved only at its extremity. The body is generally oblong,—the eyes projecting. The tracheæ are tubular or elastic, and the intestine is terminated by an expanded cloaca, provided with two small sacs which produce an acrid humour.[2]

Tribe 1st, Cicindeletæ, Lat.

This tribe corresponds to the genus Cicindela of Linnæus. Its genera are distinguished by a hook or nail, which is articulated by its base to the tip of the maxillæ. All the species have a strong head, with large eyes, projecting toothed mandibles, and a short ligula concealed behind the mentum. The labial palpi are composed of four distinct articulations, and, in common with the maxillary palpi, are generally shaggy, or somewhat clothed. The precedence is usually assigned to these insects in our systematic arrangements, from motives probably similar to those which have induced ornithologists to place the accipitrine order at the head of the class of birds. The greater proportion of the species are exotic.

Genus Manticora,[3] Fab. Tarsi alike in both sexes, and composed of cylindrical articulations. Mandibles large and arched. Head very large. Eyes small, and not greatly projecting. Back of the thorax forming a kind of semicircular lobe, prolonged as far as the posterior margin. Abdomen pediculated, almost entirely enveloped by the elytra, which are nearly heart-shaped, soldered, and laterally carinated.

M. *maxillosa*, Fab. (Plate CCXXI. fig. 1.) Entirely black, and covered with scattered hairs. The mandibles have four interior teeth, of which the third is the least. The antennæ are slender and filiform, their third articulation angular and elongated. The thorax appears as if divided into two by a transverse groove near the anterior margin, which is prolonged laterally, and beneath, as far as the origin of the fore-legs. There is no scutellum visible. The legs are large, and covered with stiff hairs.

This formidable-looking insect, which measures more than an inch and a half in length, presents the aspect of a large spider. It inhabits sandy soil in the southern parts of Africa, and is the only known species of the genus, unless the *M. pallida* of Fab. referred by Mr Macleay to his genus *Platychiles*,[4] is still to be regarded as a Manticora.

Genus Megacephala,[5] Lat. The first three joints of the anterior tarsi of the males dilated, short, almost in the form of a reversed triangle, more strongly ciliated inwards than externally. Labial palpi longer than the maxillary, —their first articulation elongated, projecting beyond the mentum, the second very short, the third very long and cylindrical, the last securiform. Labrum short and transversal, leaving the mandibles exposed.

This genus was constituted by Latreille by the removal of certain species of *Cicindelæ* of Fabricius. It occurs both in Africa and America. Those from the former country are apterous, from the latter winged. We know little more of their habits than that they are extremely active. We are acquainted with fifteen species, none of which occur in Europe.

M. *megalocephala*, Lat. Of a bronzed black colour; the mouth, antennæ, and feet pale yellow. Elytra with rows of hollow spots. From Senegal.

In the genus *Oxycheila* of Dejean (*Species Gén*. t. i. p. 15) the labrum is very large, with a projecting point, and covers the mandibles. It is formed from the *Cicindela tristis* of Fab., and is named from ὀξῦς, *pointed*, and χειλος, *lip*.

Genus Cicindela, Lin. (Plate CCXXI. figs. 2 and 5.) The first three joints of the anterior tarsi of the males dilated, elongated, nearly cylindrical, and more strongly ciliated inwards than externally. Labial palpi not surpassing the length of the maxillary; their first two joints very short, the first not passing beyond the extremity of the mentum, the third cylindrical, the last slightly enlarged at its extremity.

The name by which our present genus is distinguished is used by Pliny as synonymous with *Lampyris*, to designate a kind of luminous insect, a frequenter of corn fields.[6] It likewise appears to have been applied by ancient writers to various destructive insects which it would now be difficult to identify, although they are no doubt known to naturalists. In modern times it was originally bestowed by M. Geoffroy on the species at present classed under the genera *Malachius* and *Telephorus*, and was afterwards transferred by Linnæus to the insects above defined, as well as to other species not now included in *Cicindela*.

Their larvæ inhabit holes in the earth, the entrance to which, while the occupant lies in ambuscade, is closed by the upper portion of its head. They are exceedingly voracious, and seize with their maxillæ whatever insect prey approaches within their tyrannous grasp. The bodies of these larvæ are long, cylindrical, whitish, and furnished with six scaly feet. When approached by human footsteps, or otherwise threatened by danger, they rapidly descend into their subterranean retreats. When two of these larvæ happen to form their domiciles in the immediate neighbourhood of each other, the stronger devours the weaker, with a view to obviate any interference with his own pursuits. They seal up the entrance to their dwellings when about to change their skins or assume the state of nymph.

---

[1] So says Latreille. Some authors state the number of these eyes as only three on each side.

[2] *Règne Animal*, tom. iv. p. 358. An abstract of the anatomical characters of the insects of this division, by M. Dufour, will be found in the *Annales des Sciences Nat.* tom. viii. p. 36.

[3] Μαντιχωρα is the name of a fabulous animal mentioned by Aristotle, Ælian, and Pliny.

[4] *Annulosa Javanica*, vol. i. p. 9.

[5] From μεγας, *great*, and κεφαλη, *head*.

[6] Plin. viii. c. 26.

The perfect insects are extremely beautiful, of light and active forms, exceedingly swift in their motions, and adorned by brilliant metallic colours. The prevailing hues are different shades of golden green, spotted with white or pale yellow. They frequent dry and sandy soils, where they seem to enjoy the prevalence of bright sunshine. The species are extensively distributed over all the regions of the earth. Their organs of locomotion, and those more immediately subservient to the preservation and nutrition of the individual, are very fully developed, and present in the most perfect form all the attributes which distinguish the entomophagous or insect-eating Coleoptera. They were named by Linnæus the tigers of the insect tribes. "Though decorated with brilliant colours, they prey upon the whole insect race; their formidable jaws, which cross each other, are armed with fearful fangs, showing to what use they are applicable; and the extreme velocity with which they can either run or fly renders hopeless any attempt to elude their pursuit. Their larvæ are also equally tremendous with the imago, having six eyes, three on each side, seated on a lateral elevation of the head, which look like those of spiders; and, besides their threatening jaws, armed with a strong internal tooth, being furnished with a pair of spines resembling somewhat the sting of a scorpion, which stand erect upon the back of the abdomen, and give them a most ferocious aspect."[1] It is this last apparatus which, according to Clairville, serves the purpose of an anchor in retaining these larvæ at any desired height in their sandy cells.

Dejean's catalogue (2d edition) contains 201 species of the genus Cicindela as now restricted.

C. *campestris.* Green, with five whitish spots on the margin of each elytron, and another in the centre. The spots on the elytra vary in shape and disposition, and some of them are occasionally obliterated. The female has two fuscous spots towards the base of the elytra, and is distinguished, in addition to the more slender tarsi, by having the abdomen divided into six segments; that of the opposite sex consisting of seven, with the penultimate one more or less emarginate. This sexual distinction, first observed by Gyllenhal, exists in most genera of the tribe.

This beautiful insect frequents dry sandy places exposed to the sun, most commonly in the neighbourhood of heaths, and is distributed more or less abundantly over all parts of Britain. We have traced it through most of the Highlands of Scotland, as far as the south of Sutherland, and we doubt not that it extends to the most northern extremity of the island. It is an inhabitant of most European countries, ranging from the shores of the Mediterranean to Siberia. This is the most abundant of the British species, and the only one yet found in Scotland. The supposed species *C. Maroccana*, Fab. which occurs in Spain and along the coast of Barbary, is now regarded as one of its varieties.

Besides the preceding, five or six other species are described as British. *C. germanica*, an English insect, common in France and Germany, differs in its habits from the rest of the genus. When we attempt to seize it, it does not fly off like the others (although it is winged), but endeavours to escape by running rapidly among the herbage by which it may be surrounded.

The genus *Euprosopus* of Latreille and Dejean, of which the tarsi are equally ciliated on both sides, was established on *Cicindela quadrinotata* of Fab. The species are said to dwell on trees. In the genus *Therates*, Lat. the tarsi are nearly alike in both sexes. The internal maxillary palpi are very small, indistinct, and apparently uniarticulate. The species are confined to the eastern parts of Asia, such as Java, the isles of Sunda, and those to the north of New Holland. *C. labiata* of Fab. belongs to the genus last named, which is synonymous with *Eurychiles* of Bonelli.[2] *C. Aptera* of Olivier forms the genus *Tricondyla* of Latreille.

GENUS COLLIURIS, Lat. Fourth articulation of all the tarsi prolonged obliquely inwards in both sexes. Body narrow and elongated. Thorax almost cylindrical, narrowed anteriorly. Antennæ short, thickening more or less towards the extremity. Last article of the labial palpi dilated.

The title of *Colliuris* was bestowed originally by Degeer, upon an insect belonging to the genus *Casnonia* of Lat. It was established according to its present character by Fabricius under the name of *Collyris*, which has been altered as above by the majority of authors. These insects appear to be all provided with wings. All the species yet met with have been found in the most southern countries of Asia, and in the islands lying north of New Holland.

C. *longicollis*, Dej. Blue, sometimes tinged with violet. Thighs and hind tarsi ferruginous red. Elytra deeply punctured. This species was taken in Java by the excellent Westermann of Copenhagen, who presented it to Comte Dejean as the true *C. longicollis* of Lat. The insect so named by Latreille (*Gen. Crust. et Insect.* i. p. 174) is the *C. emarginata* of the *Species Général*, t. i. p. 165.

We shall conclude our sketch of this tribe by presenting a *synoptical view* of its most recent constitution, according to the system of Dejean.

        - slightly elongate, not exceeding the maxillary pair; last joint not securiform............ 6. *Cicindela.*
      - inflated and larger than the last. The three first joints of the anterior tarsi of the males
        - elongate and nearly cylindrical............ 7. *Dromica.*
        - somewhat elongate and flat............ 8. *Eprosopus.*
    - produced obliquely on the inner side............ 9. *Ctenostoma.*
- Mentum without a tooth in the centre of its notch.
  - Third and fourth joints of the tarsi much shorter than the first............10. *Therates.*
  - Joints of the tarsi nearly equal.
    - Three first joints of the anterior tarsi of the males dilated; the third produced obliquely on the inner side............11. *Tricondyla.*
    - Fourth joint of all the tarsi produced obliquely on the inner side in both sexes............12. *Colliuris.*

TRIBE 2D, CARABICI, Lat.

This important tribe corresponds to the old and unrestricted genus *Carabus* of Linnæus. The maxillæ are terminated simply by a point or hook, which is not articulated, as in the preceding genera. The head does not exceed the breadth of the thorax, and is more frequently somewhat narrower. The mandibles, with few exceptions, are but sparingly toothed. The ligula is usually projecting, and the labial palpi exhibit only three free articulations.[1] Many species are apterous, that is, have no membranous wings beneath the elytra. Their odour is often fetid, and their bodies exude an acrid fluid. The habits and economy both of the larvæ and perfect insects are exceedingly various. Some conceal themselves under the earth, others beneath stones, or the bark of trees. They are active in their movements, and are very generally distributed, being, however, more characteristic of temperate than equatorial regions. M. Geoffroy bestowed the generic name of *Buprestis* upon carabideous insects, on account of the injury which he supposed them capable of inflicting on cattle; and it is possible that the caustic humour with which many of them are imbued might be productive of bad effects in the event of their being swallowed along with better and more accustomed pasture. To whatever species this evil tendency was attributed, the ancients appear to have regarded its other characters with admiration, for the physicians of olden times held it as equal in virtue to Cantharides. Linnæus, however, transferred the name of Buprestis to the genus *Cucujus* of Geoffroy, although none of the latter genus in any way corresponded to the Βουπρηστις of the Greeks. The change proposed by the great reformer has been universally adopted, and the word Carabus is now most familiar to the ear of the entomologist.

As the larvæ of the Carabici dwell in subterranean retreats, a knowledge of their habits and history is difficult to acquire. The body is of an elongated form; the legs are six in number, and of a scaly texture; and the maxillæ are strong and pincer-like. With these they seize upon the larvæ of other insects, which constitute their favourite food. They are extremely voracious.

In relation to the economical purposes of the human race, the tribes now under consideration are of no great utility. It is mentioned, however, by the younger Geoffroy, that while he was collecting insects on the coast of Senegal, a negro brought him a jar containing many thousand specimens of a small carabideous species, which had evidently been previously collected by design. On inquiry he found that they were used for making *soap*, some of which, of a black colour, he afterwards examined, and found it to possess all the qualities of the European article. Olivier asks whether we could not extract from our indigenous species an alkaline matter subservient to the same ends?[2]

---

[1] In the genus Cicindela the radical joint is free, on which account the palpi are said to consist of four articulations; but among the Carabici it is adherent, and, forming only a support to the others, is not itself regarded as an articulation.

[2] *Hist. des Insectes*, vol. iii. No. 35, p. 11.

Coleoptera Pentamera.

A.

Exterior palpi not subulate or awl-shaped at their extremity; the last articulation not united with the preceding so as to form an oval body with a sharp point, or a conical one with a slender and acicular termination.

*

Two anterior tibiæ with a deep emargination in the internal side separating the two spines, which are usually placed near each other, at the extremity of that side.

SECTION 1ST, TRUNCATIPENNES.

This group derives its name from the aspect of the elytra, which appear as if cut at their extremity, or more or less truncated. This is the prevailing character, although *Odocantha dorsalis* and Dejean's new genus *Stenodactyla* present a rounded termination; but in seeking a natural system, it is the totality of organization or assemblage of characters by which we must be guided, and not by a single feature, although by its wide prevalence that feature may have been assumed, as in the present instance, for a general basis in the naming of the entire group. The two following genera present rather a sinuation than a truncation of the extremities of the elytra.

GENUS ANTHIA,[1] Weber, Fab. Terminal joint of the palpi almost cylindrical, or slightly enlarged at the extremity. Antennæ filiform. Labrum rounded, advanced, and almost entirely covering the mandibles. No tooth in the centre of the emargination of the mentum. Anterior tarsi slightly dilated in the males. Body thick, more or less elongated. Thorax more or less heart-shaped. Elytra convex, not much truncated, or nearly round at their extremity.

The insects of this genus are of considerable size. Their usual colours are black spotted with white. They inhabit the African deserts, and are not altogether unknown in those parts of Asia which extend from the Red Sea to Bengal. According to Leschenhault de Latour, they emit a caustic fluid when handled. In the males of some species the thorax is dilated and bilobed posteriorly. Both sexes are destitute of wings. Dejean's Catalogue contains seventeen species, all of which, except one, are African.

A. *maxillosa*, Lat. Black and smooth. Mandibles very long. Thorax bilobed posteriorly. This is a large insect from the Cape of Good Hope. It measures nearly two inches in length.

A. *decemguttata*, Dej. (Plate CCXXI. fig. 8.) Usually black above, the eyes brownish, a small white spot on each side of the anterior portion of the thorax. The elytra have each four deep grooves, with another in the centre common to both. These grooves are garnished with an ash-coloured or brownish down, which sometimes entirely disappears, and then each groove exhibits two rows of small excavated spots, with a longitudinal and slightly elevated line in the centre. Each elytron has also five spots formed of whitish down,—the first near the base of the exterior margin; the second a little in advance of the middle, in the second groove; the third and fourth rather behind the middle, and on the same line, in the first and third grooves; the fifth near the exterior margin, at the extremity between the second and third grooves. The under parts of the body and feet are of a more shining black. The thighs are sometimes reddish brown.

This species is extremely common at the Cape of Good Hope. It is subject to great variation in its markings, and has been described under various names in its different conditions. According to Dejean, the *Anthia quadriguttata*, Fab. which we have figured in this work (Plate CCXXI. fig. 3), is nothing more than a variety of the above, with three of the spots effaced from each elytron.

GENUS GRAPHIPTERUS,[2] Lat. Last article of the palpi cylindrical. Antennæ filiform, much shorter than the body. Labrum projecting, rounded, and nearly covering the mandibles. No tooth in the centre of the emargination of the mentum. Anterior tarsi not sensibly dilated in the males. Body large and flattened. Thorax heart-shaped. Elytra plane, broad, of a slightly elongated oval, more or less suborbicular.

We owe to Latreille the dismemberment of these insects from the *Anthiæ*, with which they were combined by Fabricius. However, they are equally apterous, inhabit the same parts of the world, and exhibit analogous colours. Although several insects of the north of Africa have been discovered in Italy and the south of Spain, the warmer countries of Europe have as yet been sought in vain for any species of either of the genera just named.

G. *multiguttatus*, Dej. (Plate CCXXI. fig. 7.) Dull black above, of a brighter black below. Thorax margined with white. The elytra with a sinuous margin of white, and eight spots on each of the same colour.

This species was brought by Olivier from Egypt, and given to his friends and correspondents under the above name, although it certainly does not agree with the description of the insect so named by the author in his *Entomologie* and the *Encyclopédie Méthodique*.

GENUS APTINUS, Bonelli. Terminal article of the palpi rather larger than the preceding, and slightly enlarged towards the extremity. Antennæ filiform. Labrum short, and leaving the mandibles exposed. No tooth, or a very small one in the centre of the emargination of the mentum. The first three articles of the anterior tarsi sensibly dilated in the males. Thorax heart-shaped. Elytra oval, increasing in breadth towards their extremity.

This genus greatly resembles *Brachinus*, with which it was combined by Fabricius, and with which it is still frequently confounded.[3] All the species belong to Africa (chiefly the Cape district) and the southern parts of Europe. Like the Brachini, they occur in groups under stones, and affect mountainous situations. They are similarly characterized by their power of emitting a penetrating vapour. The larger species inhabit tropical climates. The *A. balista*, Dej. measures from five to eight lines in length. It is black, with a fulvous throat and truncated elytra. It occurs in Navarre, and various parts of Spain and Portugal. A smaller species, of a deep black, with sulcated elytra, the antennæ and palpi fulvous, the feet russet yellow, was discovered by Dejean among the eastern Pyrenees. It is extremely common under stones on the mountains in the vicinity of Pratz de Mollo, and is named *A. pyrenæus*.

GENUS BRACHINUS,[4] Weber, Fab. This genus scarcely differs from the preceding. It is, however, characterized by the possession of wings, the anterior tarsi are not usually dilated in the males, the truncation of the elytra is rather square than oblique, and these parts are usually more parallel, or less enlarged at their extremities, than among the Aptini.

---

[1] The name Ανθιας is bestowed by Aristotle on a fish.

[2] The name probably refers to what may be construed into an occasional resemblance of written characters upon the wings,—γϱαφω and πτεϱον.

[3] All the foreign species of the above genus in the Comte Dejean's printed *Catalogue* (1st edition) are *Brachini*.

[4] Probably from Βϱαχυνω, *I shorten*, in allusion to the truncated form of the elytra.

The Brachini, as far as yet known, have no representative in Scotland. But as the southern parts of the kingdom produce five species, we are not without hope that some of these may ere long be discovered on the northern side of the Tweed. It is, however, evidently a southern genus, for of the nineteen species of the first division of Dejean, only one, the *B. Hispanus* of Kollar, is found in Europe. It was taken at the southern extremity of Spain, by an Austrian naturalist, who happened to disembark in the bay of Algesiras in the course of his voyage to Brazil. Of the twenty-one species which constitute the second division of the genus, eight occur in Europe; and of these five are English.[1] The character by which the generality of these insects are so remarkably distinguished is, that the abdomen contains peculiar organs which secrete a caustic liquor of an extremely penetrating odour. When this is propelled by the insect on any threatened danger, it produces a detonating sound, and evaporates. M. Dumeril has remarked, that when this reservoir is opened by dissection, the liquid effervesces, and evaporates instantaneously. Paper imbued with a blue vegetable dye is changed by its action, first into a reddish hue, and then into yellow. When the vesicle which contains it is placed upon the tongue, and compressed, a peculiar and rather agreeable savour is felt in the mouth. A sharp pain, however, soon follows on the spot affected, where a yellow colour becomes perceptible, similar to that produced by a drop of nitric acid. Leon Dufour has made us acquainted with the apparatus employed in the production of this fluid.[2]

It is stated by Rowlander that the Brachini are capable of producing eighteen or twenty discharges at a time. Mr Stephens has invariably found them ready to discharge their ammunition at all times, especially when roughly handled; and Mr Cooper informed him that a specimen he met with at Cobham in the spring, performed the operation no less than thirteen times in rapid succession.[3]

B. *Jurinei*, Dej. (Plate CCXXI. fig. 6.) Testaceous. The elytra black, grooved, with the lateral margins and a central spot testaceous. From Senegal.

Genus Casnonia, Lat. Terminal article of the palpi of an oval form, almost pointed at the end. Antennæ much shorter than the body, their articulations of nearly equal length,—the first being shorter than the head. Tarsi filiform; the last article at most bifid. Thorax in the form of an elongated neck, cylindrical, and very narrow anteriorly. Head nearly lozenge-shaped, prolonged and narrowed posteriorly.

The Casnoniæ are insects of singular forms, reminding the observer of the aspect of *Raphidia* and *Apoderus*. They composed the original genus *Colliuris* of Degeer; Linnæus placed them among his *Attelabi*, while Fabricius and Herbst ranged them in the genus *Odocantha*. Latreille formed the genus in which we now place them. It is synonymous with *Ophionea* of Klug.[4] Most of the species come from America. *C. cyanocephala* occurs in Bengal.

Genus Odocantha, Fab. Characters nearly the same as the preceding. Thorax elongate oval, nearly cylindrical. Head oval, narrowed behind, but not posteriorly prolonged.

O. *melanura*, Fab. Greenish blue, the base of the antennæ, chest, and feet testaceous. The elytra testaceous, with a spot of blackish blue at the extremities. The ends of the thighs black.

Dejean retains only two species in this genus, as above defined, viz. the one just described, which is the sole British species, and *O. Dorsalis*. The former insect occurs in the temperate and colder countries of Europe, in moist and marshy places; the latter is from North America.

We pass over the genus *Zuphium*, of which one species, *Z. olens*, is remarkable for occurring in France, Spain, Italy, the southern provinces of Russia, and the East Indies,—the genus *Polistichus*, of which *P. fasciolatus* is found in Britain,—the genus *Helluo* of Bonelli, of which all the species are foreign to Europe,—the genus Drypta, which has representatives in Africa, New Holland, and the East Indies, and of which *D. emarginata* is British (for a representation of *D. ruficollis*, see Plate CCXXI. fig. 9),—the genera *Galerita, Ctenodactyla, Agra, Cymindis*, Lat. (*Tarus*, Clairville, of which *T. basalis*, Gyll. occurs in the south of Scotland), and *Calleida*.

Genus Demetrias, Bon. Hooks of the tarsi dentated beneath. Terminal article of the palpi cylindrical. The first three articles of the tarsi almost triangular, the last strongly bilobed. Body elongated. Head oval, slightly narrowed posteriorly.

These little insects, as far as we know, are all European. They are frequent in spring, on briars and hedges. We have four British species, one of which, *D. obscurus*, we owe to the recent researches of Mr Newman.

Genus Dromius,[5] Bon. Resembles the preceding; but the articles of the tarsi are entire, and nearly cylindrical. The species are apterous.

The Dromii formed part of the genus *Lebia* of Latreille, till their separation by Bonelli. They are almost all European, and are commonly found under stones, and beneath the bark of trees. Britain produces about twenty species.

Genus Lebia. Hooks of the tarsi dentated beneath. Terminal article of the palpi nearly cylindrical and oval, and truncated at the end, but never securiform. Antennæ filiform. Articles of the tarsi nearly triangular or heart-shaped, the penultimate bifid or bilobed. Body short and flat. Thorax short, transversal, broader than the head, prolonged posteriorly in the middle. Elytra broad, and nearly square.

This genus, which is comparatively numerous in European species, and is likewise known in America, and more sparingly in Africa, has been divided by Bonelli into two. The type of the first division (genus *Lamprias*) is *Leb. chlorocephala*, a beautiful little insect, of a brilliant bluish green, with the base of the antennæ, legs, breast, and thorax red, the tarsi black. It occurs occasionally near Edinburgh, and has been taken as far north as Lairig, in Sutherland. The type of *Lebia* proper is *L. crux minor*, and this second division is characterized by the penultimate joint of the tarsi being bilobed, while in the first it is said to be simple. However, as far as we are able to perceive from an inspection of our north-country specimens, there is a bilobation in that part also in *Lamprias*. But other distinctive characters will be found detailed in the works of Messrs Curtis and Stephens, both of whom follow Bonelli in regarding the two divisions as distinct genera. Dejean's *Catalogue* contains sixty-four species.

Synoptical Table of the preceding Section, according to the system of Dejean.

TRUNCATIPENNES.

First Sub-Tribe.

- Last joint of the palpi usually ovate, and terminating nearly in a point. Claws
  - without teeth. Joints of the tarsi
    - nearly cylindrical, or very slightly triangular. The penultimate
      - not bilobed. Thorax
        - in the form of a lengthened neck, often cylindrical and contracted in front .... 1. *Casnonia.*
        - more or less ovate or rounded. Antennæ
          - covered with hairs .... 2. *Lasiocera.*
          - simple .... 3. *Odacantha.*
      - strongly bilobed .... 4. *Leptotrachelus.*
    - broad, flat, and triangular or heart-shaped. First joint of the antennæ
      - much shorter than the head .... 5. *Trigonodactyla.*
      - nearly as long as the head .... 6. *Cordistes.*
  - with teeth beneath .... 7. *Ctenodactyla.*
- Last joint of the maxillary palpi more or less securiform. Claws
  - without teeth. Penultimate joint of the tarsi
    - strongly bilobed .... 8. *Drypta.*
    - not bilobed. The three first joints of the anterior tarsi of the males
      - very much dilated .... 9. *Galerita.*
      - scarcely or not at all dilated. Last joint of the labial palpi
        - more or less securiform. First joint of the antennæ
          - as long as the head .... 10. *Zuphium.*
          - shorter than the head .... 11. *Polistichus.*
        - nearly cylindrical .... 12. *Diaphorus.*
  - with teeth beneath .... 13. *Agra.*

SECOND SUB-TRIBE.

- Claws with teeth beneath. Body
  - more or less elongate. Last joint of the labial palpi
    - strongly securiform, at least in the males. Penultimate joint of the tarsi
      - not bilobed............14. *Cymindis.*
      - bilobed............15. *Calleida.*
    - not securiform. Claws
      - with very large teeth............16. *Onypterygia.*
      - with small teeth. Penultimate joint of the tarsi
        - bilobed............17. *Demetrias.*
        - not bilobed............18. *Dromius.*
  - more or less wide, and depressed. Elytra nearly square. Last joint of the labial palpi
    - strongly securiform. Posterior margin of the thorax
      - forming a right angle with the sides............19. *Plochionus.*
      - produced in the middle............20. *Aspasia.*
    - not securiform. Posterior margin of the thorax
      - forming a right angle with the sides. Penultimate joint of the tarsi
        - not bilobed............21. *Lebia.*
        - bilobed............22. *Coptodera.*
- Claws without teeth. Antennæ
  - moniliform, or thickening towards the apex............24. *Helluo.*
  - filiform. Upper lip
    - short, transverse, and leaving the mandibles uncovered. Last joint of the labial palpi
      - not securiform. Elytra ovate,
        - more or less elongate
          - wings wanting............25. *Aptinus.*
          - winged............26. *Brachinus.*
        - scarcely elongate, nearly orbicular............27. *Corsyra.*
      - strongly securiform............28. *Drepanus.*
    - projecting, and covering the mandibles more or less. The tooth in the notch of the mentum
      - simple. Upper lip quadrate,
        - wider than long. Joints of the four anterior tarsi
          - more or less triangular or heart-shaped............29. *Dyscolus.*
          - nearly cylindrical............30. *Promecoptera.*
        - longer than broad. Elytra
          - rather short and wide, more or less square or ovate......31. *Thyreopterus.*
          - more or less elongate and parallel............32. *Catascopus.*
      - wanting. Last joint of the labial palpi
        - rather strongly securiform............33. *Eucheyla.*
        - not securiform. Elytra ovate,
          - scarcely elongate, nearly orbicular............34. *Graphipterus.*
          - more or less elongate............35. *Anthia.*

SECTION 2D, BIPARTITI, Lat. SCARITIDES, Dej.

Almost all the genera of this group (seventeen in number in the system of Dejean) were constituent portions of the old genus *Scarites* of Fabricius and Olivier. They possess several characters in common. The exterior palpi are not subulate or awl-shaped at their extremity. The elytra are not terminated by a truncation, but are either entire or slightly sinuated. The abdomen is separated from the thorax by an obvious intermediate neck-shaped portion.[1] The first article of the antennæ is always the largest. The anterior legs are often broad and palmated, and strongly notched interiorly. The anterior tarsi present no marked disparity in the sexes, and are unprovided with brushes beneath; but simply ciliated.[2]

In the *Coléoptères d'Europe* of MM. Latreille and Dejean, the Scaritides seem to be regarded as not carnivorous. But in opposition to this opinion, so contrary to analogy, we have the authority, as Mr Macleay has noted, of two accurate observers, MM. Olivier and Lefebre de Cerisy. The latter, who resides at Toulon, possesses peculiar facilities for acquiring a knowledge of their natural habits. He states them to be nocturnal insects of prey, which, during the day, lurk motionless in holes of the earth, and sally out at night to attack Melolonthidæ and other insects.[3]

The insects included in this division are rather strongly distinguished from the conterminous groups. As they are destined to live chiefly beneath the surface of the earth, their structure is more peculiarly adapted than that of the other Coleoptera to a subterranean mode of life. The body is narrow, the anterior thighs thickened, the tibiæ dilated, and furnished with strong spines, presenting a broad surface, well fitted to remove the soil;—the head and thorax are strong, and the latter is attached to the abdomen by a short peduncle or footstalk. In the last-mentioned particular they differ from most other pentamerous beetles, which usually have the thorax closely applied to the abdomen, and the hinder angles rectangular or even salient, which necessarily prevents any considerable degree of lateral motion. But in insects which excavate holes scarcely exceeding their body in width, some provision is necessary to enable them to turn their anterior portion in different directions, otherwise their progress would be nearly in a straight line. This object, which is analogous to that which is provided for in moles and other burrowing quadrupeds, by the flexibility of the vertebral column, is attained by the interposition of a narrow cylindrical piece between the abdomen and thorax, on which the latter moves as on a pivot, its hinder angles being rounded off that its motions may be performed with greater facility. The form of the antennæ is likewise in beautiful accordance with the habits of the insects. They are composed of nearly globular articulations attached to each other by a slender filament, bearing some resemblance to a series of beads rather loosely strung. By a structure of this kind, they are rendered greatly more pliant and flexile than in the other Pentamera (the joints of the antennæ in which are generally conical), and therefore present no obstacle to the insect's progress through a resisting medium.[4]

These insects are usually of a uniform black colour. The larva of *Ditomus bucephalus*, the only one that has been attended to, presents, according to Latreille, the same form and habits of life as those of *Cicindelæ*. They are more particularly characteristic of torrid countries, although Great Britain and the rest of Europe produce several genera.

GENUS ENCELADUS, Bon. *Scarites*, Oliv. Mentum inarticulate, soldered, covering almost all the under part of the head, strongly notched, with a bifid tooth in the centre. Terminal article of the labial palpi distinctly securiform. Antennæ filiform; the first article a little longer than the others.

The species of this genus differ from most of their section in having their anterior tibiæ unemarginate, which allies them to the *Simplicimanes* of Dejean, or *Grandipalpi* of Lat. The example figured, *E. gigas* (see Plate CCXXI. fig. 4), is a large insect of which the locality seems doubtful. Latreille believed it to come from Madagascar and equinoctial Africa, while Dejean regards it as South American.

GENUS ACANTHOSCELIS, Lat. *Scarites*, Fab. Mentum articulated, almost plane, strongly trilobed. Labrum very short, tridentated. Mandibles large, advanced, strongly toothed interiorly. Terminal article of the labial palpi almost cylindrical. Antennæ moniliform; the first article very large; the others much less, but enlarging insensibly towards the extremity. Body short and convex. Thorax convex, transverse, almost square. Elytra short, and very convex. Anterior tibiæ strongly palmated; posterior short, broad, arched, and spinous. Trochanters almost as large as the posterior thighs.

This genus is formed upon *Scarites ruficornis* of Fab. (Plate CCXXI. fig. 17), an insect above eight lines in length, black, with the palpi and antennæ ferruginous. It is native to the Cape of Good Hope.

GENUS SCARITES,[5] Fab. Mentum articulated, concave, strongly trilobed. Labrum, mandibles, and terminal article of the palpi as in the preceding genus. Body rather elongated, cylindrical, or slightly flattened. Thorax convex, almost crescent-shaped, notched anteriorly, rounded posteriorly, and frequently somewhat prolonged in the middle. Anterior tibiæ strongly palmated, posterior simple. Trochanters much shorter than the posterior thighs.

The insects of our present genus are of considerable size, of a black colour, usually shining, and are characteristic of sandy countries near the sea coast, or of districts impregnated with saline particles. They occur in the warmer countries of Europe, Asia, Africa, and America. Dejean enumerates fifty-eight species. Three are said to occur in Britain, *S. Beckwithii* of Stephens, *S. subterraneus*, and *S. lævigatus*, Fab. The two latter are, however, doubtful natives. The second is in fact an American insect (see Plate CCXXI. fig, 10),—the third is frequent in the south of France, and along the Mediterranean shores.

GENUS CLIVINA,[6] Lat. *Scarites*, Fab. Mentum articulate, concave, and trilobed. Labium slightly advanced, and cut almost square. Mandibles slightly projecting, not toothed interiorly. Terminal article of the labial palpi almost cylindrical. Antennæ moniliform; the first article as long as the two succeeding united. Body more or less elongated. Thorax square or globular. Anterior tibiæ almost always palmated.

---

[1] The foreign genus *Ozæna*, in which the peduncle is scarcely perceptible, may be regarded as an exception to the last-named character.

[2] *Species Général*, t. i. p. 355.

[3] *Annulosa Javanica*, No. i. p. 24.

[4] *Entomologia Edinensis*, p. 77.

[5] From Σκαριζῶ, *I run swiftly.*

[6] *Clivina* is the name of an augurial bird mentioned by Pliny.

These small insects are usually found under stones, by the banks of rivers, and elsewhere. They are common all over Europe, more especially in its southern parts. They also occur in Africa, America, and the East Indies. We have two British species, *C. fossor*, Gyllenhal, which is brownish black, with the mouth, antennæ, and legs rufous, the elytra punctate striate, of the same colour as the thorax,—and *C. collaris* of Herbst, of which the head and thorax are brownish black, and the elytra chesnut colour. Dejean regards the one as a variety of the other. They are described as distinct by English entomologists. We lately found a rare and interesting species, *C. arctica*, on the mountain range on the north side of the valley of Clova, in Forfarshire. It is known to occur, though rarely, in Lapland, the north of Sweden, Finland, and sometimes as far to the east as the environs of St Petersburg. It forms the genus *Leiochiton* of Curtis,[1] so named from λειος, *smooth*, and χιτον, *a covering*, the upper surface and other parts being remarkable for glossiness.

The genus *Dyschirius*, Bonelli (named from δυς, *two*, and χιϱας, *a division of the foot or leg*), which some authors do not admit as distinct from *Clivina*, contains those species of which the thorax is globular, and the anterior tibiæ palmated only at the extremity, and simple exteriorly. Sixteen species are found in Britain.[2]

GENUS DITOMUS, Bon. Mentum articulated, concave, and trilobed. Labrum slightly notched. Labial palpi slightly elongated, the terminal article almost cylindrical. Antennæ filiform, the articles elongated and nearly filiform. Thorax cordiform or crescent-shaped. Anterior tibiæ not palmated.

This genus was established by Bonelli on the *Scaurus sulcatus*, and certain *Carabi* of Fabricius, which Rossi and Olivier had placed in *Scarites*. The species are of middle size, dark or blackish in their colouring, and frequently deeply punctured. They inhabit the southern parts of Europe, the north of Africa, and the west of Asia. We have figured *D. violaceus* on the plate last referred to, fig. 16. *D. fulvipes* of Lat. a common insect in the south of France, and occurring, though rarely, as far north as Paris, has some claims to be regarded as a British species. We are acquainted with eighteen species in all.

---

[1] *British Entomology*, vol. viii. p. 346. Of the genus *Clivina*, including *Dischirius*, &c. Dejean's *Catalogue* enumerates forty-four species.

[2] We take our indications of the amount of indigenous species from Mr Stephens' *Nomenclature of British Insects*. Second edition. 1833.

Synoptical Table of the preceding Section (SCARITIDES), *according to the system of Dejean.*

- Mentum inarticulate,
  - nearly covering the under side of the head. Inner side of the anterior tibiæ
    - without a notch…… 1. *Enceladus.*
    - strongly notched…… 2. *Siagona.*
  - leaving uncovered a great part of the mouth,
    - broad, very short, and without a perceptible tooth in the centre of its notch…… 3. *Coscinia.*
    - rather narrow, short, and trilobed…… 4. *Melænus.*
- Mentum articulate, leaving great part of the mouth uncovered. Anterior legs
  - palmated. Mandibles
    - strongly dentate on the inner side. Thorax
      - convex, rounded behind, and often a little produced in the middle. Posterior tibiæ
        - straight and nearly simple…… 5. *Scarites.*
        - short, broad, bent, and covered with spines…… 6. *Acanthoscelis.*
      - quadrate, and nearly cylindrical…… 7. *Scapterus.*
      - broad, flat, nearly heart-shaped, emarginate posteriorly…… 8. *Pasimachus.*
    - very slightly or not at all dentate internally,
      - projecting greatly. Last joint of the labial palpi
        - elongate and pointed…… 9. *Oxystomus.*
        - nearly cylindrical. Thorax nearly
          - square, and somewhat cylindric…… 10. *Oxygnathus.*
          - heart-shaped, and rather flat…… 11. *Camptodontus.*
      - projecting very little…… 12. *Clivina.*
  - not palmated. Antennæ
    - short and nodose. Joints of the antennæ
      - distinct, and scarcely thickening towards the apex…… 13. *Morio.*
      - scarcely distinct, and thickening perceptibly towards the apex…… 14. *Ozæna.*
    - filiform, the joints elongate and nearly cylindrical. Labial palpi
      - somewhat elongate. Anterior tarsi
        - dilated in the males…… 15. *Carterus.*
        - alike in both sexes…… 16. *Ditomus.*
      - much elongate…… 17. *Apotomus.*

Coleoptera Pentamera.

SECTION 3D, QUADRIMANI, Lat. HARPALICI, Bon.

In this division Latreille includes those groups of Carabici which, resembling the preceding in the pointed termination of the elytra, have the four anterior tarsi dilated in the males; the first three or four articulations are in the form of a reversed heart or triangle, and are nearly all terminated by acute angles; their under part is usually furnished (excepting the *Aphoni*) with two ranges of papillæ or scales, with an intermediate linear space. The body is always winged, generally oval and arched, or convex above, with the thorax broader than long, or at most nearly isometrical, square, or trapezoidal. The head is never suddenly contracted posteriorly. The antennæ are of equal thickness throughout, or are slightly and insensibly enlarged towards the extremity. The mandibles are never remarkably strong. The external palpi are terminated by an oval or fusiform joint of greater length than that which precedes it. The tooth of the notch or emargination of the mentum is always entire,—in some wanting.[1] The legs are robust, the tibiæ spiny, and the hooks of the tarsi simple. The intermediate tarsi, even in the females, are short, and, with the exception of the dilatation, are formed nearly like the anterior. The species prefer warm and sandy situations exposed to the sun.

GENUS HARPALUS, Lat. Dej. (PLATE CCXXI. fig. 11.) The first four articles of the four anterior tarsi strongly dilated in the males, broader than long, and very decidedly triangular, or cordiform. Terminal article of the palpi somewhat elongated, slightly oval, or almost cylindrical and truncated at the extremity. Antennæ filiform. Labrum in the form of a transverse square. Mandibles slightly advanced, arcuated, and not very sharp. A simple tooth, more or less developed, in the middle of the emargination of the mentum. Body oblong, more or less elongated. Head more or less rounded, narrowed posteriorly. Thorax more or less square, cordiform, or trapezoidal. Elytra more or less elongated, and almost parallel.

The genus *Harpalus* of Latreille, as conceived in his *Genera Crustaceorum et Insectorum*, comprised all those insects which Dejean has united in the tribes *Harpaliens* and *Feroniens*, and the genera *Callistus, Oodes, Chlænius, Epomis*, and *Dinodes*, of the *Patellimanes* of the latter author. Bonelli, in his *Observations Entomologiques*, reduced the genus to the insects which now constitute the tribe *Harpaliens* of Dejean, itself consisting of twenty-eight genera. The *Harpalidæ* of the British writers include, besides our present genus, many genera of the sections afterwards mentioned under the names of *Simplicimani* and *Patellimani*.

The genus Harpalus, even as now restricted and above defined, is very extensive, and probably contains nearly one half of the species of the section. The larvæ of these insects, as far as we are acquainted with them, dwell beneath the ground. Their form is conico-cylindrical; their head large, armed with strong mandibles, resembling those of the perfect insect; the posterior part of their body exhibits a membranous tube, terminated by a prolongation of the anal region, and two fleshy articulated appendages. Their metamorphoses are likewise subterranean. The Harpali are distributed over all the earth. They are, however, obviously more abundant in the temperate and even boreal regions of the northern hemisphere, than in equinoctial or southern countries. Comte Dejean's collection contains 179 species, while Mr Stephens enumerates (including the doubtful kinds) 58 species as indigenous to Britain, besides 15 *Ophoni*, which Dejean combines with Harpalus.

We may name as one of the most abundant of the genus *H. ruficornis*, of a pitchy-black colour, the antennæ and legs rufous, the elytra pubescent striated, the interstices punctured. This insect is spread over all Europe. We took it at Cape Wrath. It occurs in Siberia. M. Goudot brought it from Northern Africa.

H. æneus is distinguished by various shades of green above, with a brassy or coppery lustre; the under side black; external margin of the elytra punctulated, the antennæ and legs rufous. This species is extremely variable. It is generally of a rich bronzed green; the males highly polished, the females more obscure, sometimes brownish black. Mr Kirby once took a specimen of this insect, which he immersed in hot water, and was surprised to observe what he at first supposed an intestine thrust itself forth; on a nearer inspection he found it was an intestinal worm, thicker than a horse-hair, and of a brown colour.[2]

This group (the Quadrimani), in the system of Dejean (where it is named Harpaliens), includes many minor genera not recognised in the *Règne Animal*, and contains the genera *Tetragonoderus* and *Pelecium*, which in Latreille's arrangement belong to other sections. As we cannot enter into a detailed exposition of the characters of those genera, we shall here exhibit Dejean's latest views by means of a synoptical table.

HARPALICI.

FIRST SUB-TRIBE.

Mentum trilobed.

Antennæ	filiform	1. *Pelicium.*
	moniliform	2. *Eripus.*

SECOND SUB-TRIBE.

Mentum deeply notched.

This sub-tribe may be separated into two divisions.

FIRST DIVISION.

Antennæ moniliform.

The tooth in the notch of the mentum	simple. Last joint of the labial palpi	ovate	3. *Cratocerus.*
		cylindric, and truncated at the extremity	4. *Somoplatus.*
	wanting		5. *Daptus.*

---

[1] The ligula or anterior portion of the mentum is always, according to Latreille, in this as well as in the two following genera, remarkably salient, obtuse or truncated at the end, and is accompanied by two distinct membranous paraglossæ in the form of auricles (oreillettes).

[2] For the other British species we must refer the reader to the works of Messrs Stephens and Curtis. We have described such as occur near Edinburgh in our *Entomologia Edinensis*. The characters of the foreign kinds are detailed in Dejean's *Species Général*.

Second Division.

Antennæ filiform.

May be divided into two subdivisions.

First Subdivision.

Notch of the mentum with a bifid tooth in the middle.

- Body
  - flat and rounded..6. *Cyclosomus.*
  - elongate..7. *Promecoderus.*

Second Subdivision.

Tooth in the notch of the mentum simple or wanting.

- Last joint of the palpi securiform..8. *Axinotoma.*
- Last joint of the palpi not securiform. The four first joints of the intermediate tarsi of the males
  - more or less triangular or heart-shaped. Last joint of the palpi
    - more or less cylindric or ovate, and truncated at the extremity. Fourth joint of the four anterior tarsi of the males
      - triangular or heart-shaped. Head
        - more or less quadrate or triangular, not contracted behind. The tooth in the notch of the mentum
          - more or less obvious. Upper lip
            - emarginate. The tooth in the notch of the mentum
              - obtuse..9. *Acinopus.*
              - strong and very acute..10. *Cratacanthus.*
            - quadrate..11. *Paramecus.*
          - wanting. Mandibles
            - more or less pointed. Upper lip
              - deeply notched..12. *Cratognathus.*
              - almost quadrate..13. *Agonoderus.*
            - obtuse, and not salient..14. *Barysomus.*
        - more or less rounded and triangular, and contracted behind. The tooth in the notch of the mentum
          - wanting. Mandibles
            - obtuse, and not salient..15. *Amblygnatus.*
            - more or less pointed. Four first joints of the anterior tarsi of the males
              - obviously dilated. First joint of the four anterior tarsi of the males
                - as wide as the following. Last joint of the palpi
                  - ovate and almost inflated. First joint of the anterior tarsi of the females
                    - not dilated...16. *Platymetopus.*
                    - dilated.......17. *Gynandropus.*
                  - cylindric, or very slightly ovate 18. *Selenophorus.*
                - smaller than the following..19. *Anisodactylus.*
              - very slightly dilated..20. *Bradybænus.*
          - more or less obvious. Mandibles
            - salient and pointed..21. *Geodromus.*
            - projecting but little. The four first joints of the intermediate tarsi of the males
              - obviously dilated. The four first joints of the four anterior tarsi of the males
                - as long as wide, and slightly triangular..22. *Hypolithus.*
                - wider than long, and distinctly triangular or heart-shaped. First joint of the anterior tarsi of the females
                  - dilated..23. *Gynandromorphus.*
                  - not dilated..24. *Harpalus.*
              - very slightly dilated..25. *Geobænus.*
      - deeply bilobed..26. *Stenolophus.*
    - terminating in a point..27. *Acupalpus.*
  - broad and nearly square..28. *Tetragonoderus.*

SECTION 4TH, SIMPLICIMANI.

This section resembles the preceding so far as regards the termination of the elytra;[1] but the two anterior tarsi only are dilated in the males, without however forming a square or orbicular pallet; sometimes the first three articles are obviously broader, and the succeeding one is in that case always much less than its antecedent; sometimes the latter and the two preceding ones are larger, almost equal, and in the form of a reversed or triangular heart. The joints of the four following tarsi are more slender and elongated, almost cylindrical, or in the form of a lengthened and reversed cone.

The *Simplicimani* of Latreille consist of genera belonging to the tribe *Carabiques Feroniens* of Dejean, with the addition of *Tetragonoderus*, Dejean (Harpalici), *Catascopus*, Kirby (Truncatipennes), and a few others.

GENUS ZABRUS, Clairville. The first three articles of the anterior tarsi dilated in the males, broader than long, strongly cordiform. Terminal article of the palpi almost cylindrical, and truncated at the extremity. Antennæ filiform, and but slightly lengthened. Labrum of a square form, broader than long, slightly notched anteriorly. Mandibles little advanced, rather strongly arcuated, almost obtuse. A simple tooth in the middle of the emargination of the mentum. Body thick and convex. Thorax transverse, square, trapezoidal, or rounded on the sides. Elytra convex, rarely elongated, frequently very short, almost parallel, and rounded at the extremity.

These insects are usually found under stones, or marching about the fields, occasionally on the stalks of grass or other herbage. We are acquainted with about twenty species, of which not more than two are British. The majority of the others occur in the southern parts of Europe. There is one from Teneriffe.

GENUS FERONIA, Lat. Dej. The first three articles of the anterior tarsi dilated in the males, broader than long, and strongly triangular or cordiform. Terminal article of the palpi more or less elongated, cylindrical, or slightly securiform. Antennæ filiform, more or less lengthened. Labrum square, broader than long, sometimes almost transversal, quadrate anteriorly, or slightly notched. Mandibles more or less advanced, and more or less arcuated and pointed. A bifid tooth in the middle of the emargination of the mentum. Thorax more or less cordiform, rounded, square, or trapezoidal, never transverse. Elytra more or less elongated, oval, or parallel. Intermediate tibiæ always straight.

A great variety of opinion is maintained by entomologists regarding the distribution of the component parts of this extensive genus. Bonelli, in the synoptical table annexed to the first part of his *Observations Entomologiques* (in 1809), published the generic characters of *Platysma, Pœcilus, Abax, Molops, Percus, Melanius*, and *Pterostichus*. At an after period MM. Megerle and Ziegler established *Argutor, Steropus, Cophosus*, and *Omaseus*, the latter genus, it is believed, corresponding to *Melanius* of Bonelli. All these were admitted provisionally into the first edition of Comte Dejean's *Catalogue*, published in 1821. In the third volume, however, of the *Species Général* of that great collector, he observes as follows: "Ma collection depuis cette époque s'etant considérablement augmentée, je me suis trouvé souvent tres-embarassé pour placer dans ces différents genres les espèces qui je recevais, surtout les exotiques, et quelquefois plusieurs d'entre elles me paraissaient intermédiaires entre deux genres, et appartenir autant à l'un qu'à l'autre. Plus je recevais d'insectes, plus je me trouvais embarassé, et lorsque je voulus classer definitivement toutes mes espèces dans chaque genre, et etablir les caractères de chacun de ces genres, après plusieurs essais infructueux, je finis par être convaincu que cela était réellement impossible." Dejean then thought of following the example of Sturm, who reduces (in his *Deutschlands Fauna*) all the genera above named to those of *Abax, Molops, Pterostichus*, and *Platysma*; but after a deliberate re-examination, even these did not appear sufficiently marked; and he finally determined to combine them all in one under the name of FERONIA, a term previously used in a comprehensive sense by Latreille in the first edition of the *Règne Animal*.

The genus *Feronia*, then, of Dejean is one of the most extensive in the coleopterous order, containing above 230 species. It is subdivided by the last-named author into ten sections, corresponding to the same number of genera as established by Bonelli, Megerle, Ziegler, and Sturm.

According to Latreille's views, the genus is divisible into three groups as follows: 1*st*, The species, generally winged, of which the body, more or less oval, is a little convex or arcuated above, with the antennæ more filiform, the head proportionally narrower, and the mandibles somewhat less projecting. In their habits these insects approach the genera *Harpalus* and *Zabrus*. Such are the *Amaræ*, of which the thorax is transverse (and which Dejean admits as a distinct genus); the *Pœcili*, where it is almost as long as broad, and where the rather short antennæ have the third article compressed and angular; and the *Argutores*, which resemble the Pæcili, but have proportionally shorter antennæ, with the third joint not angular.

2*d*, The species usually furnished with wings, but of which the body is straight, plane, or horizontal above, with the head nearly as wide as the body. Such is the genus *Platysma* of Bonelli, to which Latreille unites *Omaseus* of Ziegler and Dejean, and *Catadromus* of Macleay.

3*d*, This division contains Feroniæ, analogous to those of the preceding one in their general characters, but distinguished by the want of wings.[2]

We shall conclude by observing that our English entomologists have adopted all those minor genera, in so far as they are applicable to the British species, and have even proposed several others of still more limited application. We regret that our necessarily narrow limits prevent our entering into minute details.[3] We shall merely indicate a few of the species. *F. madida* is shining black, the elytra ovate, rather convex, subpunctate-striate, with a puncture on the third interstice a little behind the middle. This is the *F. concinna* of Sturm and Dejean. A variety occurs with the thighs and sometimes the tibiæ rufous; it constitutes the *F. madida* of the latter author. They are not distinct. Both varieties are in this country among the most common of coleopterous insects, occurring beneath stones, at the roots of trees, &c. both on low grounds and on mountains. They seem less common in Germany than in any other country in Europe. *F. nigrita* is also of frequent occurrence in all parts of Britain. It is of a shining black, the thorax subquadrate, narrowed behind, the elytra with obsoletely punctured striæ, and three impressed dots on the disk. *F. orinomum* is likewise shining black, often faintly tinged with brassy; elytra striated, with more than four impressed dots on the disk of each. By the comparison of an extensive series of specimens of this insect which we have collected in various parts of Scotland, we are satisfied that *F.* (*Omaseus*) *Bulwerii* of Stephens is not specifically distinct. A species frequent under stones in woods and fields, and the last which we shall here mention, is *F. melanaria.* It is black, apterous, moderately convex, the thorax with a bistriated fovea in each of its posterior angles, the elytra with striæ nearly impunctate.

---

[1] As usual, there are exceptions to the rule:—"Plusieurs Carabiques simplicimanes," says Latreille, "ont l'extrémité de leurs élytres fortement sinuée au bout, et se distinguant à peine, sous ce rapport, des *Troncatipennes*." (Note to *Règne Animal*, t. iv. p. 399.)

[2] For a further exposition of Latreille's views, see *Règne Animal*, tom. iv. p. 395.

[3] For the arrangement of the indigenous species, see Mr Stephens' *Nomenclature of British Insects*, 2d edition.

Genus Broscus, Panzer. *Cephalotes,* Bon. First three articles of the anterior tarsi dilated in the males, broader than long, and decidedly cordiform. Terminal article of the labial palpi elongated and slightly securiform. Antennæ filiform, and but slightly lengthened. Labrum of a square form, broader than long, almost transverse. Mandibles slightly arcuated, and rather sharp. A simple tooth in the middle of the emargination of the mentum. Thorax cordiform, convex, and much contracted posteriorly. Elytra rather long, slightly oval, or parallel.

This genus was established by Bonelli on the *Carabus cephalotes* of Fabricius, and was also distinguished about the same period by Panzer under the name of *Broscus.* We adopt the latter term as more familiar to the English collectors. Of the five species with which we are acquainted, two belong to Europe, one to the north of Africa, one to Mount Sinai, and the fifth to Asia Minor. They are all of considerable size, and bear a resemblance to the genus *Steropus* of Megerle.

The only British species is *B. cephalotes,* which is of an elongated form, black, with the head thinly punctured, and the elytra very finely punctate-striate. It occurs in sandy places over many parts of Britain; and in the vicinity of Edinburgh is plentiful under stones, and marine rejectamenta, on the shore between Portobello and Musselburgh. We found it as far north as Keoldale, near Cape Wrath. The attitude this insect assumes when disturbed is rather peculiar. The two anterior pair of legs are brought close together, and extended straight outwards at right angles with the under surface of the body. The hind legs are bent upwards, and project in a similar way from the opposite surface. The antennæ are drawn close to the sides of the thorax, and the mandibles extended to their utmost stretch, while a considerable degree of rigidity is imparted to the whole. It takes this posture most readily in cold weather; at other times, when more active, it prefers seeking safety by flight, or by burrowing in the sand.[1]

"The habit of these insects," it is elsewhere observed, "is very curious. They are found only in the sand on the sea shore, and live in dens about three inches deep and half an inch wide, which are made in a diagonal position in the sand, where it is mixed with decomposed stalks of *Elymus arenarius.* They appear to rove during the day occasionally; but upon any alarm they run swiftly to their dens, projecting from the mouths of which their heads may be seen watching for prey. On holding another beetle to the hole, the one within would immediately seize hold of it with its jaws, and continue so tightly fixed as to suffer itself to be drawn out without quitting its hold. They appear to be very ferocious insects; and, from the number of elytra and other parts strewed about the sand, it may be supposed that they prey on each other."[2] The latter observation, we may remark, applies to many insects; although the human race (certainly in that respect the most noted) have been supposed to present the only instances of identical species waging war upon each other.

> Even tiger fell and sullen bear,
> Their likeness and their lineage spare.
> Man only mars kind nature's plan,
> And turns the fierce pursuit on man.[3]

The natural position of the genus Broscus seems to be that assigned it by Mr Curtis, between the Scaritides and the species which in the *Entomologia Edinensis* is placed at the head of the genus *Feronia,* viz. *F. madida* (*Steropus madidus,* Meger.). In common with the former, *Broscus* possesses an elongated form, rather short stout legs, and a pedunculated thorax, which adapt it to a subterraneous mode of life. In the latter the thorax is also pedunculated, and the legs thick and strong, while the more rigid structure of the antennæ, admitting less easily of being applied to the sides of the thorax to facilitate progression in a cylindrical hole, together with the general configuration of most of the other parts, assimilate it more decidedly to the other Feroniæ, to which its habits perfectly correspond.

Genus Mormolyce, Hagenbach.[4] Exterior palpi very short; the terminal article cylindrical, and almost rounded at the extremity. Antennæ setaceous, almost as long as the body; the third article as long as the two following. Labrum almost square, notched anteriorly. Mandibles short, arcuated, rather sharp, and toothed interiorly. A simple tooth in the middle of the emargination of the mentum. Body remarkably depressed. Head narrow, elongated, much prolonged posteriorly. Thorax almost lozenge-shaped. Elytra flat, thin, greatly dilated, much wider and longer than the abdomen.

The aspect of this genus is one of the most remarkable with which we are acquainted. We place it among the *Simplicimani* (*Feroniens*) in accordance with the example of Latreille and Dejean, the latter of whom observes, "J'ai placé cet insecte près des *Sphodrus,* mais ce n'est qui provisiorement, car j'ignore de quelle maniere les tarses sont dilatés dans les males, et même s'ils ne sont pas semblables dans les deux sexes." In regard to its locality he further observes, "D'après M. Hagenbach, elle se trouve dans la partie occidentale de Java; d'autres personnes croient qu'elle vient de la Cochin-Chine."[5] Our recent acquisition of an extensive series of specimens of the only known species enables us to determine both of those doubtful points. The tarsi are alike in both sexes, and our collection was brought from Java.

The insect above alluded to (*Mormolyce phyllodes,* Plate CCXXI. fig. 13[6]) measures nearly three inches in length and an inch and a half across the dilated portion of the elytra. It is entirely of a blackish-brown colour, somewhat paler on the edges of the abdomen. It is furnished with wings, and the elytra have the appearance of being reticulated. The figure just referred to will convey an accurate idea of its form. We have supplied the principal collections of Europe with this rare and singular insect, of which, says Dejean, to whom we had the pleasure to transmit a pair, "il est presque impossible de se faire la moindre idée par la description." He also terms it "un insecte extraordinaire, qui parait appartenir au premier aspect à la famille des *Mantis,* mais qui est cependant un Coléoptère, et même un veritable Carabique, ainsi qu'il est facile de s'en convaincre par ses caractères generiques."

Passing over the genus *Sphodrus,* of which *S. leucophthalmus* is the only British species, we come to

Genus Calathus, Bon. First three articles of the

Coleoptera Pentamera.

anterior tarsi dilated in the males. Hooks of the tarsi toothed beneath. Terminal article of the palpi elongated, almost cylindrical, and truncated at the extremity. Antennæ rather elongated, filiform, and slightly compressed. Labrum of a square form, broader than long, very slightly notched anteriorly. Mandibles not much advanced, slightly arcuated, and rather sharp. A bifid tooth in the middle of the emargination of the mentum. Thorax trapezoidal, or almost square, little, if at all, contracted posteriorly. Elytra rather elongated, slightly oval, little contracted anteriorly, and rounded at the extremity.

This genus, as Mr Stephens observes, presents a peculiar outline from the shape of the head, trapeziform thorax, and elliptic elytra, by which it is readily distinguished from the neighbouring genera. The species usually reside among short herbage on banks, and are frequently observed upon quick-hedges.[1] They are generally of a black or brown colour, rarely metallic. They are extremely active in their movements. The only species we shall here notice is the *C. microcephalus* of Dejean,[2] which we discovered in the summer of 1832 in the highlands of Forfarshire, Perthshire, and Aberdeenshire. It forms an addition to our British species, and is distinguishable from the others by the following characters:—Shining black; antennæ, palpi, legs, and margin of the thorax testaceous; the thorax rather long, somewhat narrowed behind, with the hinder angles obtuse; elytra not much elongate, with slender impunctate striæ, the second and third from the suture with two impressed points. In size it nearly agrees with the very common *C. melanocephalus*. On the continent it occurs in Sweden, France, Switzerland, and Germany, chiefly in woods and on mountains.

Here follows the synoptical table of the preceding section, according to the system of Dejean, and including many genera of which we cannot give the detailed characters.

FERONIENS, Dej. (Chiefly) SIMPLICIMANI, Lat.

DIVISION FIRST.

First joint of the anterior tarsi dilated, at least in the males.

This division contains only one genus........ 1. *Stenomorphus.*

DIVISION SECOND.

The two first joints of the anterior tarsi dilated in the males.

- Tooth in the notch of the mentum
  - wanting........ 2. *Omphreus.*
  - simple........ 3. *Melanotus.*
  - bifid. Last joint of the labial palpi
    - ovate, and terminating nearly in a point. Thorax
      - flat, nearly square, slightly or not at all contracted behind........ 4. *Pogonus.*
      - convex, heart-shaped, considerably contracted behind........ 5. *Cardiaderus.*
    - nearly cylindrical, truncated at the tip, and slightly securiform. Thorax
      - convex, nearly ovate........ 6. *Baripus.*
      - flat, contracted behind, more or less heart-shaped........ 7. *Patrobus.*

DIVISION THIRD.

Three first joints of the anterior tarsi dilated in the males.

FIRST SUBDIVISION.

Claws dentate beneath.

- Tooth in the notch of the mentum
  - simple........ 8. *Dolichus.*
  - bifid. Last joint of the labial palpi
    - not securiform. Thorax
      - contracted behind, and more or less heart-shaped........ 9. *Pristonychus.*
      - trapezoidal or nearly square; scarcely or not at all contracted behind........ 10. *Calathus.*
      - oval, rounded behind........ 11. *Pristodactyla.*
    - securiform........ 12. *Taphria.*

---

[1] *Illus. of Brit. Ent.* vol. i. p. 98.

[2] *Species Général*, t. iii. p. 78.

Second Subdivision.

Claws without teeth.

- Third joint of the antennæ as long as the two following united. Elytra
  - much wider than the abdomen .... 13. *Mormolyce.*
  - nearly of the same breadth as the abdomen .... 14. *Sphodrus.*
- Third joint of the antennæ shorter than the two following united. Three first joints of the anterior tarsi in the males
  - considerably elongate, very slightly triangular, or nearly square. The tooth in the notch of the mentum
    - simple. Thorax more or less
      - heart-shaped; the hinder angles always distinct. Elytra
        - flat, elongate-ovate, without distinct anterior angles .... 15. *Platynus.*
        - slightly convex, ovate or elongate-quadrate; the anterior angles always distinct .... 16. *Anchomenus.*
      - rounded; without distinct posterior angles .... 17. *Agonum.*
    - wanting .... 18. *Olisthopus.*
  - scarcely elongate, distinctly triangular or heart-shaped. Mentum
    - trilobed or slightly notched. Last joint of the maxillary palpi
      - not securiform,
        - almost cylindrical, and truncated at the tip. Last joint of the labial palpi
          - triangular, or very strongly securiform .... 19. *Trigonotoma.*
          - slightly securiform. Middle lobe of the mentum
            - produced and nearly pointed .... 20. *Catadromus.*
            - scarcely produced and almost truncated .... 21. *Lesticus.*
          - almost cylindrical. Middle lobe of the mentum
            - nearly wanting .... 22. *Distrigus.*
            - rounded .... 23. *Abacetus.*
        - elongate, and terminating nearly in a point .... 24. *Drimostoma.*
      - strongly securiform .... 25. *Microcephalus.*
    - deeply notched. The tooth in the notch
      - simple or bifid. Three first joints of the anterior tarsi of the males
        - without appendages beneath. Last joint of the maxillary palpi
          - cylindric or securiform. Body
            - more or less elongate or depressed; Thorax more or less heart-shaped, rounded, quadrate, or trapezoidal. The tooth in the notch of the mentum
              - bifid. Last joint of the labial palpi
                - not securiform. Middle legs
                  - not at all or slightly arched .... 26. *Feronia.*
                  - much arched .... 27. *Camptoscelis.*
                - strongly securiform .... 28. *Myas.*
              - simple. Thorax
                - convex or heart-shaped. Mandibles
                  - wide, and projecting little .... 29. *Cephalotes.*
                  - narrow, and projecting much .... 30. *Stomis.*
                - flat and nearly square .... 31. *Abaris.*
            - short, thick, and convex; thorax transverse. Last joint of the labial palpi
              - pretty strongly securiform .... 32. *Rathymus.*
              - nearly cylindrical. The tooth in the notch of the mentum
                - bifid .... 33. *Pelor.*
                - simple .... 34. *Zabrus.*
          - slightly ovate .... 35. *Amara.*
        - furnished with appendages beneath .... 36. *Lophidius.*
      - wanting. Thorax
        - more or less square or heart-shaped, not at all or very slightly transverse 37. *Antarctia.*
        - transverse, rounded on the sides, slightly produced in the middle behind .... 38. *Masoreus.*

Coleoptera Pentamera.

SECTION 5TH, PATELLIMANI, Lat.

This section is chiefly distinguished from the preceding by the mode in which the two anterior tarsi are dilated in the males; the first joints (usually the first three, then the fourth, in others only the first two) sometimes square, sometimes partly of that form, and the others heart-shaped or reversed triangular, but always rounded at their extremity, and not terminated, as in the preceding sections, by acute angles,—form an orbicular pallet or lengthened square, of which the under surface is usually furnished with brushes or close set papillæ, without any intermediate vacancy. The legs are generally long and slender. The thorax is frequently narrower throughout its whole extent than the abdomen. The species frequent, for the most part, moist places on the banks of rivers.

In the *Règne Animal* this section is composed of the *Patellimani* of Dejean, of a portion of his *Feroniens* (Gen. *Dolichus, Platynus, Agonum, Anchomenus, Patrobus*), and of the genus *Pelicium* of Kirby, referred to the *Harpaliens* in the *Species Général*. It is subdivided by Latreille into two principal groups.

a. Head insensibly contracted behind.

GENUS AGONUM, Bon. First three articles of the anterior tarsi dilated in the males, longer than broad, and slightly triangular or cordiform. Terminal article of the palpi lengthened, cylindrical, more or less oval, and truncated at the extremity. Antennæ filiform, rather elongated. Labrum slightly convex, of a square form, broader than long, almost transversal. Mandibles not much advanced, slightly arcuated, rather sharp. A simple tooth in the middle of the emargination of the mentum. Thorax more or less rounded, without obvious posterior angles. Elytra oval, more or less elongated.

Of this genus *A. sexpunctatum* is a beautiful species, of which the head and thorax are golden green, the elytra copper-red, finely striated, and impressed with six large punctures. There is only one recorded instance of its being taken in Scotland,—on the banks of the water of Leith, a little to the west of Edinburgh.[1] Several other species are, however, common in Scotland. There are about thirty kinds in Britain; and Dejean's collection contains fifty-six.

The genus ANCHOMENUS is nearly allied to the preceding, but the labrum is plane, the thorax more or less cordiform, with obvious posterior angles. The body is not so flat. We are acquainted with above forty kinds, of which not more than five inhabit Britain. We consider *Platynus angusticollis* as belonging to this genus.

In the genus CHLÆNIUS of Bonelli, the tooth of the emargination of the mentum is bifid, the external maxillary palpi are terminated by an almost cylindrical article, slightly restricted at the base, that of the labial being in the form of a reversed and lengthened cone. There are 115 species of this extensive genus, of which about eight are as yet recognised as British. They are ornamental insects, being frequently adorned with green, and burnished with a metallic lustre. They are spread over almost all the earth,—Europe, Asia, Africa, and America. They seem, however, rare in the southern division of the new world, and, as far as we know, have not yet been found in New Holland.[2] *Carabus saponarius* of Olivier,[3] which is used in Africa instead of soap, belongs to the genus *Chlænius*. It was brought from Senegal by M. Geoffroy, fils.

In the genus LICINUS the first two articles of the anterior tarsi are dilated in the males. The terminal article of the palpi is broad and securiform, and there is no tooth in the middle of the emargination of the mentum. The species are confined to Europe and the north of Africa. In the genus BADISTER the first three articles of anterior tarsi are dilated in the males, and the terminal article of the palpi is oval. The species are confined to Europe.

b. Head suddenly contracted behind the eyes.

This division of the *Patellimani* contains the genera PELICIUM of Kirby and CYNTHIA of Lat., both from South America, and three other genera, viz. PANAGÆUS (see Plate CCXXI. fig. 15), of which the head is very small compared to the size of the body,—LORICERA (Ibid. fig. 14), of which the first joint of the antennæ is robust, almost as long as the three following united, the second and fourth short, with strong hairs, the third longer than the second, likewise furnished with hairs,—and PATROBUS.

Synoptical Table of the preceding Section, according to the System of Dejean.

PATELLIMANI.

- Notch of the mentum with a tooth in the middle. Anterior tarsi dilated in the males
  - at most in the two first joints. Last joint of the maxillary palpi
    - strongly securiform. The tooth in the notch of the mentum
      - simple........ 1. *Eurysoma.*
      - bifid........ 2. *Panagæus.*
    - not securiform........ 3. *Geobius.*
  - in the three first joints. The tooth in the notch of the mentum
    - simple. Antennæ
      - beset with hairs........ 4. *Loricera.*
      - simple. Last joint of the palpi
        - not securiform,
          - rather elongate, ovate, and terminating nearly in a point........ 5. *Callistus.*
          - elongate, and truncated at the tip........10. *Oodes.*
        - strongly securiform........ 6. *Vertagus.*
    - bifid. Last joint of the palpi
      - elongate, and
        - truncated at the apex........ 7. *Chlænius.*
        - strongly securiform........ 8. *Epomis.*
      - short and slightly securiform........ 9. *Dinodes.*
- Notch of the mentum without tooth in the middle. Mandibles
  - pointed. Last joint of the palpi
    - not securiform........ 11. *Rhembus.*
    - rather strongly securiform........12. *Dicælus.*
  - obtuse. Anterior tarsi dilated in the males,
    - in the two first joints........13. *Licinus.*
    - in the three first joints........14. *Badister.*

Coleoptera Pentamera.

* *

Anterior tibiæ without an emargination on the internal side, or presenting one that begins close to their extremity, or that does not extend on their anterior face, and forms merely an oblique and linear canal.

SECTION 6TH, GRANDIPALPI, Lat. SIMPLICIPEDES, Dej.

In this section of the *Carabici* the ligula is often extremely short, terminated in a point in the centre of its summit, and accompanied by pointed paraglossæ. The mandibles are robust. The terminal joint of the exterior palpi is usually larger, compressed into the form of a reversed triangle, or hatchet-shaped in some,—almost spoon-shaped in others.[1] The eyes are prominent. The elytra are entire, or simply sinuated at their posterior extremity. The abdomen is usually bulky when compared to the other parts of the body. These Carabici are for the most part of great size, often richly coloured, or ornamented with metallic splendour. They are active in their movements, and voracious in their dispositions. They are divisible into three groups.

1*st*, Body always thick, without wings; labrum always bilobed; terminal article of the external palpi always very large; emargination of the mentum toothless; internal side of the mandibles entirely dentated (or nearly so) throughout their length.

GENUS PAMBORUS, Lat. Tarsi similar in both sexes. Terminal article of the palpi securiform. Antennæ filiform. Labrum bilobed. Mandibles but slightly projecting, greatly curved, strongly toothed interiorly. Mentum almost plane, slightly notched anteriorly. Thorax almost cordiform. Elytra elongate oval.

This genus is formed upon a large insect from New Holland, the *P. alternans*, which we have represented in Plate CCXXII. fig. 1. It is the only one yet known. In a collection received some time ago from New Holland (transmitted to the Edinburgh Museum by Colonel Lindsay), and submitted to our examination by Professor Jameson, there is either a distinct species, or a strongly marked variety,—the third and fourth striæ of the elytra being much more regular than usual. Comte Dejean, with whom we communicated on the subject, regards it as a species.

GENUS CYCHRUS, Fab. Tarsi similar in the two sexes. Terminal article of the palpi very strongly securiform, almost spoon-shaped, and more dilated, in the males. Antennæ setaceous. Labrum bifid. Mandibles narrow, and toothed interiorly. Mentum strongly notched. Thorax cordiform, little, if at all, raised at the edges, and not prolonged posteriorly. Elytra fixed, carinated laterally, and embracing the sides of the abdomen.

C. *rostratus* is common all over Britain, and is sometimes taken at a great height upon the mountains. *C. elongatus* and *attenuatus* are said to occur in England. We have represented that discovered by Professor Bonelli among the mountains of the north of Italy, Plate CCXXI. fig. 22. Eleven species are known in all. They are found in Europe, Asiatic Russia, and North America.

The genus SPHÆRODERUS of Dejean is formed by dismemberment of the preceding. It is a sub-genus peculiar to America. We have represented *S. nitidicollis*, Plate CCXXI. fig. 19.

2*d*, Body thick, and mostly apterous, as in the preceding genera, but the emargination of the mentum provided with an entire or bifid tooth, and the mandibles armed at most with one or two teeth situated at their base.

GENUS PROCERUS, Megerle. Tarsi similar in both sexes. Terminal article of the palpi very strongly securiform, and more dilated in the males. Antennæ filiform. Labrum bilobed. Mandibles slightly curved, very sharp, smooth, with only a single tooth at their base. A very strong tooth in the middle of the emargination of the mentum. Thorax almost cordiform. Elytra elongate oval.

The Proceri are large and remarkable insects, the giants of the European Carabici. In regard to their colours, they are either entirely black, or black beneath, with a tinge of blue or green above. The elytra are extremely rough. They appear to inhabit exclusively the mountains and forests of Carniola, Illyria, Turkey in Europe, parts of Hungary, the south of Russia, the Caucasus, and Asia Minor. *P. Duponchelii*, Dej. was lately taken in the environs of Athens. M. Fischer is of opinion (*Entomographie de la Russie*), that *P. tauricus* (Plate CCXXI. fig. 21) and *Caucasicus* are, the former the male, the latter the female, of the same species; but Dejean now possesses both sexes of each, and regards them as distinct. The synonymes of the species, however, are still confused and contradictory.

GENUS CARABUS, Lin. Fischer, Dej. The first four articles of the anterior tarsi dilated in the males, the first three very strongly, the fourth often more slightly. Terminal article of the palpi more or less securiform, and more dilated in the males. Antennæ filiform; the third article cylindrical, and scarcely longer than the others. Labrum bilobed. Mandibles slightly curved, more or less sharp, smooth, with only a single tooth at their base. A very strong tooth in the middle of the emargination of the mentum. Thorax more or less cordiform. Elytra more or less elongate oval. Wings not fitted for flight.

The great genus *Carabus* of Linnæus originally contained the whole of those extensive natural groups which now constitute the family of Carabici, with which we are still engaged. Even as now restricted, it is one of the most numerous with which the entomologist is concerned, and is rendered highly interesting from the size and beauty of many species. The genera with which the *Carabi*, as above defined, bear the most direct relations, are *Procerus*, *Procrustes*, *Calosoma*; but, as Dejean observes, they differ from the first by the anterior tarsi, dilated in the males,—from the second by the form of the labrum and mentum,—and from the third by several characters easily perceived on comparison.

The greater proportion of the true Carabi, which form a very interesting and well-observed genus, occur in the comparatively temperate countries of Europe, the Caucasus, Siberia, Asia Minor, Syria, and the north of Africa, as far south as the 30th degree. A few are also found towards the two extremities of America, and it is not improbable that others may be ascertained to inhabit the intermediate countries.[2] A very fine species (*C. cribellatus*, Adams) is native to the polar regions of Siberia;[3] and Sir Joseph Banks captured another as far south as Terra del Fuego;[4] of the latter circumstance, Dejean, who has done so much to illustrate the family, does not appear to be aware. "Depuis long temps je supposais néanmoins qu'on devait les retrouver à l'extrémité de l'Amérique Méridionale; M. Eschscholtz, qui fait pour la seconde fois le tour du monde avec le Capitaine Kotzebue, vient de confirmer cette supposition, et dans une lettre écrite à M. le Comte de Mannerheim il lui annonce

---

[1] It is often more dilated in the males than in the other sex, particularly in *Procerus*.

Coleoptera Pentamera.

qu'il a trouvé au Chili un véritable Carabe."[1] None of the genus, however, has as yet been found either in Southern Africa or New Holland. Count Dejean possesses 163 species, which he has arranged in sixteen divisions. In the first thirteen are comprised all those of which the elytra are arched or convex, in the three last those in which they are plane. The nature of the surface of the elytra furnishes the other secondary characters, in pretty close accordance with the methods of Bonelli and Clairville.[2] Among the continental species, the *C. rutilans* (Plate CCXXI. fig. 20), *hispanus*, &c. exhibit perhaps the most ornamental examples within the range of the European Coleoptera; and our own *Carabus nitens*, an inhabitant of the heathy wastes, yields to few, even of the exotic species, in its lustrous and metallic splendour.

The name of Carabus (Καραβος), applied generically by Linnæus to so vast a group, occurs in Aristotle's history of animals, and denotes sometimes a winged coleopterous insect, at other times a species of crustaceous animal. Latreille supposes it to be a contracted form of *Scarabæus*. In addition to the characters already given, we may mention that the species of the genus, as now restricted, are all of considerable dimensions. Their colours are usually black with a tinge of purple, or greenish with a golden hue. The form of the body is elongated; the head, always narrower than the thorax, is generally of greater extent forwards than transversely, and is borne almost in a horizontal position. The eyes are globular, and behind them the head assumes a narrow neck-like form. The mandibles, which are strong and pointed, are usually destitute of dentation, and may be observed to cross each other when the insect is in a state of repose. The thorax is narrower than the abdomen, is bordered with a slightly recurved margin, and is almost always emarginate in its basal line; its superior portion (strictly speaking the *prothorax*) is more extended than the inferior parts, and covers posteriorly the scutellum of the mesothorax, which, naturally but slightly developed, presents to view its summit only. The elytra are also margined after the manner of the thorax, and their upper surface, rarely smooth, is variously characterized, according to the species, by striæ, furrows, depressed points, or rows of bead-like elevations. The true or membranaceous wings are either wanting or exist in a very rudimentary condition. The species therefore are incapable of flight; but, to make amends for this deficiency, their legs are strong and lengthened, the trochanter is greatly developed, and the tarsi of the anterior pair (in the males) are dilated, with their first four articulations spongy on their inferior face.

All the species are eminently voracious and carnivorous. They not only prey upon the soft bodied and defenceless caterpillars, and on all other insects weaker than themselves, but they even seize upon and devour their own species. They usually avoid strong light, are partial to a certain degree of moisture, and conceal themselves during the heat of the day beneath stones, among mossy herbage, in garden rubbish, or under the stems or within the hollows of fallen trees. We have noted the usual habits of each of the species in the descriptions which follow; and, in regard to their general distribution, we may observe, that their principal seat appears to be the north temperate zone, that they are extremely rare in the warmer regions of the earth, and probably disappear altogether within the tropics. Their larvæ and metamorphoses are but slightly known. Many of the perfect insects exhale a penetrating and fetid odour, and when touched exude a dark-coloured caustic humour.

Mr Stephens enumerates nineteen species of British Carabi. The claims, however, of three or four of these (such as *C. purpurascens, convexus, auronitens*) to be regarded as truly indigenous, are extremely doubtful. The occurrence of an insect on our island shores is sometimes accidental, and results from the fortuitous impulsion of winds or waves. It is well that the visits of these erratic strangers should be recorded, as they afford an interesting illustration of the extreme extent in one direction of their geographical range; but they cannot on that account be considered as "children of the soil." We shall here give a few brief notices of the Scottish species.

C. *catenalatus*, Fab. Oblong-ovate, black, the margins of the thorax and of the elytra violaceous; elytra with interrupted crenated striæ, and three rows of impressed dots, the spaces between the dots slightly elevated. Common throughout Scotland, both on mountains and in plains.

C. *monilis*, Fab. Oblong-ovate, thorax coppery, elytra brassy-green or violaceous, with three series of oblong tubercles, and three equal elevated lines between them. The colour of this species is very variable. It is rare in Scotland, and we have not yet observed it during our excursions to the northern counties.

C. *arvensis*, Fab. Ovate, greenish coppery, or brassy above, elytra with three series of oblong tubercles, and three crenulated lines between them, the central line rather elevated. Not as yet known to be generally spread over Scotland, but collected at several distant points. Pentland Hills, Island of Arran, vicinity of Jedburgh.

C. *cancellatus*, Fab. *C. morbillosus*, Leach. Oblong, metallic green or brassy, elytra with three rows of oblong tubercles, and a single smooth elevated line between them. Not unfrequent in decayed wood and under stones. Neighbourhood of Edinburgh; parish of Durness, Sutherland.

C. *hortensis*, Fab. Ovate, thorax black, margined with purple, elytra brassy brown, with three rows of excavated dots. Common near Edinburgh, occurring in gardens, pathways, &c., during spring and summer, and pretty widely spread over Scotland, but much rarer in the northern counties than *C. catenalatus*, and not partaking with that species in the height of its occasional localities. Only one specimen found in Sutherland among many scores of other species of the genus.

C. *violaceus*, Linn. Elongate, black, the margins of the thorax and of the elytra violaceous; elytra dull black, granulated. An elegantly shaped species, not unfrequent in Scotland, in woods and fields, and among garden rubbish. It also occurs among the mountains, and has been taken at Cape Wrath.

C. *glabratus*, Fab. Oblong, entirely black, the elytra very finely granulated, so as to appear smooth and shining. Inhabits the Pentland Hills, but is very scarce in our southern districts. Not unfrequent among the Grampians and other mountain ranges in the north, where it occurs on the summits of the highest hills. Taken at Cape Wrath, and in other parts of Sutherland.

C. *nitens*, Linn. Ovate, head and thorax golden coppery, elytra brilliant green, margined with coppery-red, and having three blackish ribs on each. Under side of the body, and legs, shining black. This, though one of the smallest, is the most richly adorned of the British Carabi, and is one of the most beautiful of coleopterous insects. It is pretty generally spread over the upland and moorish districts of Scotland. We did not find it in

---

[1] *Species Général*, t. ii. p. 33.

[2] *Règne Animal*, t. iv. p. 412.

Sutherland, but we have specimens from the shires of Mid-Lothian, Lanark, Dumbarton, Argyll, Perth, and Forfar. It is always regarded as a valuable acquisition, on account of its extreme beauty.

C. *clathratus.* Oblong-ovate, of a dark brassy hue, thorax rather square, the posterior angles not much produced, the elytra with three elevated lines, and a triple series of deep golden excavations. This is one of the largest and finest of the British Coleoptera. It has hitherto been regarded as a very rare insect, but a closer examination of the wilder districts will probably bring it into more frequent view. We were the first to take it in Scotland,—which we did many years ago, and in considerable numbers (nine or ten specimens in a few days), in the island of Colonsay, the hospitable habitation of John Macneill, Esq. It has been since taken by Mr Macleay in Caithness. Capt. Graham, R. N. and others, also captured several specimens in different parts of Sutherland (near Invershin, on the point of Tongue, and the vicinity of Lairig), in the month of August 1833; and Mr George Little has collected it for some seasons at Ormsary, on the mainland of Argyllshire. On the continent this beautiful insect is found in Siberia, Sweden, Hungary, Italy, and the south of France, especially in the environs of Montpellier. It varies singularly in regard to the development of the true or membranaceous wings. Those which occur in the south of Europe are large, and furnished with wings; those of Sweden and Siberia are apterous, and of smaller size.

GENUS CALOSOMA,[1] Weber, Fab. First four articles of the anterior tarsi dilated in the males; the first three very strongly, the fourth often more slightly. Terminal article of the palpi very slightly securiform. Antennæ filiform; the third article slightly compressed, sharp on the outer edge, and sensibly longer than the others. Labrum bilobed. Mandibles broad, very slightly curved, more or less sharp, transversely striated, without obvious teeth on their interior. A strong tooth on the middle of the emargination of the mentum. Thorax short, almost transversal, more or less rounded. Elytra usually of a square form, more or less elongated, rarely oval or rounded. Wings most frequently fit for flight.

This genus is very widely distributed. There are about thirty species in all, spread in different proportions over Europe, Asia, Africa, and America. *C. sycophanta* (Plate CCXXII. fig. 2) and *inquisitor* have occurred in Britain. The genus is as yet unknown in Scotland.

3d, The third and last division of the *Grandipalpi* of Latreille presents an assemblage of characters which clearly distinguish its component parts from those of the two preceding. Most of the species are winged. The anterior tarsi of the males are always dilated. The labrum is entire. The exterior palpi are merely somewhat dilated or thicker at the extremity, the last joint being in the form of a reversed and elongated cone. The internal side of the mandibles presents no tooth deserving of notice; the one in the middle of the emargination of the mentum is bifid. The centre of the superior margin of the ligula is elevated to a point. On the internal side of the anterior tibiæ of several there is a short emargination, or one of the two spurs is inserted higher than the other, so that in this respect these *Carabici* are somewhat ambiguous, and might be placed, as well as those of the ensuing section, immediately after the *Patellimani.* They usually inhabit moist situations. A few, such as *Omophron,* seem to connect their tribe with that which follows,—the aquatic Carnivora.

In some in which the body is flattened, or convex and suborbicular, the eyes are of ordinary size; the antennæ linear, and generally consisting of elongated and almost cylindrical joints; the external sides of the maxillæ are bearded, and the two internal spines of the two anterior tibiæ are on a level at their origin; these tibiæ have merely a simple longitudinal canal. In LEISTUS, Frœhlich (*Pogonophorus,* Lat.), the exterior palpi are much elongated, the mandibles are dilated at their base, the head is suddenly narrowed behind the eyes, and the antennæ are long and slender. All the species belong to Europe, and the greater proportion are found to occur in Britain. NEBRIA, Lat. resembles *Leistus,* but the palpi are much shorter, the mandibles not dilated, the head not restricted, and the antennæ proportionally thicker, and composed of shorter articulations. Several of the species, such as *N. Gyllenhalii, brevicollis,* &c., are classed by English entomologists in the genus *Helobia* of Leach. In OMOPHRON of Lat. (see Plate CCXXI. fig. 18), the first joint only of the two anterior tarsi is dilated in the males.

In other genera the body is tolerably thick, and the eyes large and prominent; the antennæ are slightly enlarged near the extremity, and composed of short joints, mostly in the form of a top or reversed cone; one of the two spines of the internal extremity of the two anterior tibiæ is inserted higher than the other, with a notch between them. The four or first three joints of the anterior tarsi of the males are in general but slightly dilated. The palpi are more elongated. They occur chiefly by the sides of rivers in Europe and in Siberia. We may here place the genus ELAPHRUS,[2] in which the thorax is convex, rounded, narrowed posteriorly, and nearly of the same length as the head. The elytra are convex and almost parallel. This genus was separated with great propriety by Fabricius from Cicindela of Linn. It is constituted by a few small species, generally distinguished by metallic lustre, and of which one of the most beautiful, *E. lapponicus,* was lately presented to us by Professor Lyell, the learned author of the *Principles of Geology.* It has been hitherto only known as a native of Lapland, and was discovered by Mr Lyell on the north-west side of Catlaw, a mountain in Forfarshire, on a spot nearly 2000 feet above the level of the sea. Several of the smaller species which formerly belonged to *Elaphrus* now form the genus *Notiophilus* of Dumeril. Such are *N. aquaticus, biguttatus,* &c.

---

[1] Καλος, *beautiful,* and σωμα, *body.*

[2] Fabricius derives the name from Ελος, *a marsh.* We think it may be more plausibly traced to Ελαφρος, *light, active.*

Synoptical Table of the preceding Section, according to the System of Dejean.

SIMPLICIPEDES.

- Elytra carinated on the sides, and embracing a part of the abdomen. Lateral edges of the thorax
  - scarcely or not at all elevated, and not produced. Anterior tarsi
    - alike in both sexes........ 1. *Cychrus.*
    - dilated in the males........ 2. *Sphæroderus.*
  - much elevated, and produced behind........ 3. *Scaphinotus.*
- Elytra not carinated on the sides, and not embracing the abdomen. Upper lip
  - with two or three lobes. The tooth in the notch of the mentum
    - wanting........ 4. *Pamborus.*
    - simple. Anterior tarsi
      - not dilated in the males........ 5. *Procerus.*
      - dilated in the males. Upper lip
        - trilobed........ 7. *Procrustes.*
        - bilobed. Third joint of the antennæ
          - cylindric, and scarcely longer than the others........ 8. *Carabus.*
          - compressed, sharp exteriorly, and sensibly longer than the others........ 9. *Calosoma.*
  - entire. The tooth in the notch of the mentum
    - wanting........ 11. *Pteroloma.*
    - simple........ 5. *Tefflus.*
    - bifid. Last joint of the palpi
      - scarcely or not at all securiform. Antennæ
        - nodose and elongate. Anterior tarsi dilated in the males,
          - in the three first joints,
            - nearly in a square form, more or less elongate........ 10. *Leistus.*
            - triangular or heart-shaped........ 12. *Nebria.*
          - in the first joint only........ 13. *Omophron.*
        - short and rather thick. Last joint of the palpi
          - elongate and obconic. Anterior tarsi dilated in the males,
            - in the three first joints........ 14. *Pelophila.*
            - in the four first joints. Thorax
              - quadrate, and wider than the head........ 15. *Blethisa.*
              - rounded, and of the same width as the head........ 16. *Elaphrus.*
          - short, and somewhat inflated........ 17. *Notiophilus.*
      - rather strongly securiform........ 18. *Metrius.*

B.

SECTION 7TH, SUBULIPALPI, Lat. Dejean.

These form of themselves the second general division of the Carabici, and are distinguished from the preceding sections by the form of the exterior palpi, of which the penultimate obconical joint is united to the following, forming with it a common oval or fusiform body, terminated either gradually or suddenly in a point, or in the manner of an awl. The two anterior tibiæ have always an emargination on the inner side. The first two articles of the anterior tarsi are alone dilated in the males. This division contains only three genera, as follows:

- Last article of the palpi
  - at least as large as the preceding. Penultimate article of the maxillary palpi
    - as large as the last....1. *Trechus*.
    - smaller than the last..2. *Lachnophorus*.
  - much shorter than the preceding..3. *Bembidium*.

Of the two great tribes, viz. CICINDELETÆ and CARABICI, with the principal genera of which we have just been engaged, there are 2494 species enumerated in the last edition of the Catalogue of Comte Dejean. We come now to

TRIBE 3D, HYDROCANTHARI, Lat.

This tribe is composed of the undivided genera *Dytiscus* and *Gyrinus* of the old writers. Their feet are adapted for swimming; the last four being compressed, ciliated or laminiform, and the last two at a distance from each other. The mandibles are almost entirely covered. The body is always oval, the eyes but slightly prominent, and the thorax much wider than long. The terminal hook of the maxillæ is curved from its base; those at the extremity of the tarsi are often unequal.

All these aquatic Coleoptera pass both their first and final stage of existence in the fresh and placid waters of lakes and marshes, or the undisturbed parts of tranquil rivers, and are distributed over all the countries of the earth, wherever such localities occur, from Greenland to Van Diemen's Land.

The old genus *Dytiscus* (Plate CCXXII. fig. 3 and 4) embraced a vast assemblage of aquatic insects which the more minute observance of modern times has partitioned into many genera. They form a truly amphibious family; for although water is their favourite element, they survive for a long time on moist land, and most of them fly about in the evening and morning twilight, and even during the darkness of the dewy night, with great power and celerity. They vary considerably in size, according to the species, some being extremely small, while others measure between one and two inches in length. They are fierce and voracious in their habits, preying indiscriminately upon whatever smaller and softer tribes they are able to subdue. They are frequently observed resting on the surface of the water, with their legs expanded, their heads downwards, and the terminal segment of their bodies in contact with the air. It is thus that they carry on the process of breathing, for they cannot respire except by bringing a globule of atmospheric air in contact with the stigmata, which are placed on the sides of the abdomen, just beneath the outer margins of the elytra. Being specifically lighter than water, when they feel the necessity of respiration they have nothing to do but to allow themselves to float to the surface, where, by a peculiar action of the tips of the elytra and the terminal segment of the body, a portion of air is brought into contact with the stigmatic openings. The bodies of the larvæ of these insects (Plate CCXXII. fig. 6) consist of eleven well-defined segments. The head is large, flattish, covered above by a scale or shield marked down the centre by a longitudinal furrow. On each side there are five or six black tubercles which are regarded as eyes, and anterior to the eyes are placed the antennæ, consisting of three articulations. The mouth is armed with a pair of strong, horny, curved, sharp-pointed mandibles, which serve to seize and transfix the prey. According to Swammerdam and Degeer, these organs are pierced so as to act as suckers, by means of which the animal juices are absorbed. Near the extremity of the abdomen two delicate appendices may be perceived, pointing obliquely downwards. By means of these the larva appears to suspend itself occasionally from the surface of the water when it wishes to respire. The principal stigmatic openings are at the end of the abdomen, and consist of two small cylindrical bodies, which, when the creature floats, come in contact with the air, and communicate with the tracheal vessels, which are seen to traverse beneath the skin on either side of the body. The movements of these insects in the larva state are effected in the water, partly by the legs and partly by an undulatory motion of the tail. They prey upon other larvæ, such as those of dragon-flies, ephemeræ, gnats, &c. As an instance of their great voracity, it may be mentioned that we once observed one of the larger kinds transfix and suck out the juices of thirteen well-grown tadpoles in a single day. When the period of their transformation has arrived, they leave the water and bury themselves in the moist soft earth of a neighbouring bank. There they work for themselves an egg-shaped chamber, in which they assume the nympha state. (Plate CCXXII. fig. 9.) How long they remain in that condition is not very precisely known, from the difficulty of rearing them in confinement throughout their entire changes, but it is believed that the insect is not long of making its appearance in the perfect state. It may then be kept alive in a tumbler for several seasons, and the larger kinds (*Dytisci* proper) soon assume a certain degree of tameness and familiarity, will follow the finger around the walls of their transparent prison, and, coming to the surface at an accustomed signal, will demand, according to their own mode of expression, a young earthworm, or a piece of fresh beef or mutton; for on these and several other articles they feed from the first with extreme, and as it were accustomed greediness.[1] They may thus be said to be aquatic in the larva state, terrestrial in that of nymph, and amphibious in their winged condition.

GENUS DYTISCUS,[2] Linn. Antennæ setaceous, longer than the head. External palpi filiform, or a little enlarged towards their extremity. Anterior tarsi patelliform in the males, the middle pair with their basal joints dilated; the hind pair long, thick, and tapering to the apex, where there are two very small claws. Plate CCXXII. fig. 3 and 4.[3]

The Dytisci are large aquatic beetles, the characteristic habits of which have been sketched in our preceding general observations. We are acquainted with about fourteen species, six or seven of which inhabit Britain.

---

[1] Esper kept a living specimen of *Dytiscus marginalis* in a glass vessel for three years and a half. It fed on beef.

[2] From δυτης, *a diver.*

[3] Figure 5 of the plate above referred to represents the head of *D. serricornis*, a species remarkable for the anomalous form of the antennæ. (See *Nov. Act. Acad. Scient. Stockh.* xx. 1, 3.)

D. *punctulatus* seems to be the most common in Scotland. It thrives well in confinement, and will live for a year or two in any small vessel, feeding on earthworms and shreds of beef or mutton.[1] *D. marginalis*, when recently captured, has a smell resembling liquorice. It is said to kill Hydrus piceus, which is a much larger and apparently stronger insect, by piercing it between the head and thorax, the only part of the body which is unprotected. Esper asserts that it is much affected by atmospheric changes, and that it indicates these, when in a state of confinement, by the height at which it remains in its jar.

In the genus Colymbetes[2] of Clairville (fore leg, Plate CCXXII. fig. 7), the four anterior tarsi have their three first joints equally dilated in the males, and forming collectively a small pallet in the form of a lengthened square. The antennæ are at least as long as the head and thorax. The eyes are slightly or not at all projecting. Many of these insects are common in ditches and small brooks, and their habits resemble those of the preceding genus. There are about seventy species in all, of which one half inhabit Britain.

The genus Acilius was first proposed by Dr Leach in the *Zoological Miscellany*. It is distinguished by the great flatness of the species; by the hairy elytra of the females, which have but few striæ; and by the basal joint of the tarsi in the second pair of legs not being dilated.

In the genus Hygrobia[3] of Lat. the antennæ are shorter than the head and thorax, the body is ovoid, and very thick in the middle, and the eyes are prominent. (Plate CCXXII. fig. 11.)

In Hydroporus[4] of Clairville, the four anterior tarsi are nearly similar, and spongy underneath, in both sexes, and are composed apparently of only four joints, the fifth being deficient, or very small, and concealed along with a portion of the fourth in a cleft of the third articulation. The scutellum is not apparent.[5] In Noterus[6] of the same author, the antennæ are slightly dilated in the middle, and the last joint of the labial palpi is emarginate, and appears forked. In Haliplus,[7] Lat. there are only ten distinct joints in the antennæ; the external palpi are fusiform, or have a more slender termination, tapering to a point; the body is convex and ovoid beneath; all the tarsi are filiform, composed of five cylindrical joints, and have nearly the same form in both sexes.

All the preceding genera of *Hydrocanthari* belonged to the old genus *Dytiscus*. The remainder of the tribe are comprised in the

Genus Gyrinus,[8] Linn. Antennæ shorter than the head, the basal joint very large, and produced externally into a triangular ciliated lobe, the rest forming a clavate mass, attached by a short peduncle to the upper side of the first joint. Anterior legs rather long, and projecting like arms; the others compressed, ciliated, and formed for swimming. (Plate CCXXII. figs. 8 and 12.)

In this genus the body is oval and generally very glossy. The head is sunk in the thorax almost to the eyes, and these are large, and divided by a horny process or border, in such a way that there seems to be two above and two below. Only seven joints of the terminal portion of the antennæ are distinctly visible. The singular auriform shape of these organs induced Latreille to form the Gyrini into a family along with *Parnus*, under the name of *Otiophori*. But at an after period that great entomologist approximated the genus to the *Dytiscidæ*, thereby correcting the error he had previously committed of confounding, as Mr Macleay observes, a relation of analogy with one of affinity. The Gyrinidæ live in society, and several species are extremely common on our ponds, and ditches by the way side. They swim flat upon the surface, with their shining backs above water, chasing each other in circles, or darting about in more irregular gyrations. When hemmed into a corner of the pond, they make their escape by darting beneath the surface, carrying along with them a portion of air, which shines like quicksilver. Britain produces several species of this genus. They are known in England by the name of whirlgigs. These insects fly well, and transport themselves with ease and rapidity from place to place. The females deposit their eggs on the leaves of aquatic plants. The eggs are very small, lengthened in the form of little cylinders, and of a white colour tinged with yellow. According to the observations of Degeer, they produced minute six-footed larvæ in the course of eight days, which swam in the water, or crept along the sides of the vessel in which they had been deposited. Neither he nor Roesel, however, could succeed in rearing them to a state of completion. These larvæ (Plate CCXXII. fig. 17) exhibit rather a singular aspect, and at first sight resemble small Scolopendræ. They are of a dingy white or greyish colour, and their clear transparent skin permits the view of their internal structure. Their bodies are long, slender, cylindrical, and divided into thirteen rings, which are deeply incised. The head is oval, very much elongated, and flattened both above and below. It is armed in front with a pair of comparatively large curved jaws, tipped with brown, which, when closed, meet with their points in advance of the head, but are capable of wide extension. The structure of these parts demonstrates a carnivorous disposition. The antennæ are very delicate, divided into four articulations, and equal the head in length. The first segment of the body is nearly twice as long as the others, and the three pairs of feet are attached to the first three segments. The eight following rings are garnished with very singular, long, slender, transparent filaments, which float in the water without being apparently under the guidance of the animal. From their resemblance to the gills of the Phryganeæ and Ephemeræ, it is probable that these are the respiratory organs. The twelfth or penultimate segment of the body is furnished with four of these filaments, of much greater length than the preceding, and covered with long hairs or secondary filaments. The last segment, which is much less than the others, is terminated by four long and remarkable hooks, placed parallel to each other, with their points bent beneath inwards. The whole body seems filled with little globules of air, which are in frequent motion, sometimes towards the head and sometimes towards the other extremity. Modeer has described the transformations of these creatures in the Memoirs of the Royal Academy of Sweden. About the beginning of August, according to that author, the larvæ leave the water, and, crawling up the stems of reeds or other aquatic plants, they are transformed into nymphs, beneath the envelope of a small cocoon, pointed at both ends, and formed of a substance resembling grey paper. Towards the end of the same month the perfect insect is

excluded, and immediately jumps into the water. Modeer adds, that the cocoons are very frequently found pierced by the ovipositor of an ichneumon fly.

Great Britain produces nine species of the genus *Gyrinus* (including *G. villosus*, which belongs to *Potamobius*, Leach[1]). There are twenty-six in all. They are rare in Africa and Asia, but are widely spread over Europe, North and South America, and New Holland. We have received a large species from Java. They are also found at the Cape and the Isle of France.

The most common and best-known species in this country is *G. natator*, of an oval form, bluish-black, extremely glossy, the inflected margin of the elytra, apical segments of the abdomen, and legs, ferruginous. This agile little creature appears to have been rather a favourite object of observation with the entomologist. "Water, quiet still water," says Mr Knapp, "affords a place of action to a very amusing little fellow (*Gyrinus natator*), which, about the month of April, if the weather be tolerably mild, we see gamboling upon the surface of the sheltered pool; and every schoolboy who has angled for minnows in the brook is well acquainted with the merry swimmer in his shining black jacket. Retiring in the autumn, and reposing all the winter in the mud at the bottom of the pond, it awakens in the spring, rises to the surface, and commences its sports. They associate in small parties of ten or a dozen near the bank, where some little projection forms a bay, or renders the water particularly tranquil; and here they will circle round each other, without contention, each in his sphere, and with no apparent object, from morning until night, with great sprightliness and animation; and so lightly do they move on the fluid, as to form only some faint and transient circles on its surface. Very fond of society, we seldom see them alone, or, if parted by accident, they soon rejoin their busy companions. One pool commonly affords space for the amusement of several parties, yet they do not unite or contend, but perform their cheerful circlings in separate family associations. If we interfere with their merriment they seem greatly alarmed, disperse or dive to the bottom, where their fears shortly subside, as we soon again see our little merry friends gamboling as before. This plain, tiny, gliding water-flea seems a very unlikely creature to arrest our young attention; but the boy with his angle has not often much to engage his notice; and the social active parties of this nimble swimmer, presenting themselves at these periods of vacancy, become insensibly familiar to his sight, and by many of us are not observed in after-life without recalling former hours—scenes of perhaps less anxious days; for trifles like these, by reason of some association, are often remembered when things of greater moment pass off and leave no trace upon the mind."[2] Wordsworth has likened a beetle to

> A mailed angel on a battle day;

and Messrs Kirby and Spence describe the subjects of our present notice as being "covered with lucid armour,—when the sun shines they look like little dancing masses of silver and brilliant pearl."[3] They however exhale a disagreeable and rancid odour.[4]

FAMILY II.—BRACHELYTRA, LAT.[5]

In this, the second family of Pentamerous Coleoptera, Latreille places those genera which have only a single palpus to each maxilla, or four in all, including the labial pair. The antennæ, sometimes of equal thickness, and at others slightly enlarged at the extremity, are usually composed of lenticular or graniform articulations; the elytra are much shorter than the body (from which circumstance they derive their name), and the latter is narrow, elongated, generally depressed, with the coxæ of the two anterior legs very large. The posterior extremity of the body is provided with two vesicles, which are protruded at will.

These Coleoptera composed the great genus *Staphylinus* (of Linnæus) before its subdivision by more recent writers. Ancient authors appear to have bestowed the name of *Staphylinus* on certain species, which, from the characters assigned them, and their reputed injurious effects on horses, we can scarcely refer to any of the modern genera of brachelytrous insects. Mouffet, however, having satisfied himself that some ancient passage did apply with sufficient correctness, made use of the term Staphylinus in relation to the present group; and whatever may have been its original application, its meaning is now no longer ambiguous in the modern systems. The genus, as constituted by Linnæus, was first dismembered by Fabricius of two of its component groups, under the generic names of *Pæderus* and *Oxyporus;* and in still more recent times numerous other subdivisions have taken place, which have raised the original genus to the rank of an ordinal section or comprehensive family.

Some writers regard the Staphylini as forming the passage from the Coleoptera in general to the Forficulæ or ear-wigs, which compose the first genus of the *orthopterous* order. In their habits they somewhat resemble the Silphæ and Necrophori. They have usually a large, flattened head, strong mandibles, short antennæ, and a thorax as wide as the abdomen, which is long, narrow, and generally depressed. The elytra are very short and truncated, although they still suffice to cover the long membranous wings, which, when not in use, are compactly folded. The upper portion of the segments of the abdomen, being exposed in consequence of the shortness of the elytra, is, contrary to the usual rule among the coleopterous tribes, of as firm a consistence as that beneath. From the terminal segment of the abdomen two vesicles are protruded or retracted at the pleasure of the animal, and from these, when irritated, a subtile vapour makes its escape with a strong odour of sulphuric ether. "Though most of the micropterous species," Mr Kirby observes, "have a fetid smell, yet there are some exceptions to this amongst them. One species (*S. suaveolens*, K. MS.), related to *S. micans*, Grav. which I once took, smelt precisely like a fine high-scented ripe pear; another, *Oxytelus morsitans*, like the water-lily; a third, *O. rugosus*, like water-cresses; and lastly, a fourth (*S. fuscipes*) like saffron." M. Leon Dufour has described the apparatus by which these odours are produced.[6] The insects of this family, when attacked or touched, elevate the extremity of their abdomen, bend it in various directions, and frequently protrude the vesicles above alluded to. They also use the point of the abdomen to close or unfold their wings. The tarsi of the two anterior legs are frequently broad and dilated, and their coxæ, as well as those of the intermediate pair, are very large. The species usually occur in damp places, under stones, in earth, and excrementitious matters. Some live in mushrooms and fungi, or in rotten wood, while a few of the smaller species are found on flowers. They are all swift, active, and voracious.

[6] *Ann. des Sciences Nat.* t. viii. p. 16.

The larvæ bear a close resemblance to the perfect insect. In figure they more nearly resemble an elongated cone, the base of which is formed by the head; the terminal segment is prolonged into a tube, and is accompanied by two conical and hairy appendages. Their food and habits of life are very similar to those of the imago.

According to M. Dufour, the only essential difference between the alimentary canal of the brachelytrous tribes and that of the carnivorous Coleoptera consists in the absence of the crop. The first stomach is small and destitute of folds; the second is very long and pilose; the intestine is extremely short. The biliary vessels are inserted at the same lateral point as in the Carnivora, and present in some species, near the middle, a knot or vesicle, not observable in any other insects. Their sexual apparatus differs greatly from that of the carnivorous Coleoptera.[1]

Many of the species of this family are of minute dimensions, and a knowledge of their names and characters is of difficult attainment. Many more of the described species than have been hitherto collected no doubt exist in Britain, and many of the Scandinavian species will probably be discovered to inhabit Scotland. There is every reason, indeed, to believe that an assiduous entomologist would here reap a rich harvest among a tribe of insects which seem characteristic of, though by no means peculiar to, temperate or northern countries. Notwithstanding the obscurity in which many of our smaller species are still involved, Great Britain already possesses nearly *eight hundred* recorded species of brachelytrous insects, while the last edition of Dejean's Catalogue (1833), including European and exotic kinds, gives only 789.[2]

In a family so extensive, and of late so minutely subdivided, we must satisfy ourselves with a few brief indications of the principal genera. It is divided into five great sections.

1*st*, FISSILABRA.

In these the head is completely exposed, and separated from the thorax (which is sometimes square or semi-oval, sometimes rounded or cordiform, and truncated) by a neck or sensible restriction. The labrum is deeply bilobed.

In OXYPORUS,[3] Fab. (Plate CCXXII. fig. 13), the maxillary palpi are filiform, those of the labium terminated by a large and lunate article. The antennæ are large, perfoliate, and compressed. The anterior tarsi, of which the last (and next to it the second) joint is the longest, are not dilated. The species inhabit *Boleti* and *Agarici*. In ASTRAPÆUS, Grav. the four palpi are terminated by a larger and nearly triangular article. The anterior tarsi are greatly dilated, and the first and last joints are the longest. In STAPHYLINUS, Fab. (the true *Staphylini*), all the palpi are filiform, and the antennæ are inserted between the eyes, above the labrum and mandibles. Some, particularly the males, have the anterior tarsi greatly dilated, and the antennæ rather distant at the base; the length of the first joint being equal at most to that of a fourth of the whole number. The head is but slightly elongated. These, according to the views of some authors, alone constitute the genus.[4] Our largest British species, *S. Olens* (*Goerius*, Leach), is placed here by Latreille, along with a more ornamental example, *S. erythropterus* (Plate CCXXII. fig. 16). Others are linear, with the head and thorax in the form of an elongated square, and the antennæ approximated at the base, and strongly geniculate and granose. The anterior tarsi are either not at all or but slightly dilated. The anterior tibiæ are spinous, with a stout spine at the extremity. The labrum is small. These form the genus *Xantholinus* of some authors. In PINOPHILUS of Grav. the palpi are filiform, but the antennæ are inserted before the eyes, outside the labrum, and near the exterior base of the mandibles. In LATHROBIUM (Plate CCXXII. fig. 21) of the same author (*Pæderus*, Fab.), the palpi are terminated suddenly by a pointed and often indistinct article, much smaller than the preceding; those of the maxillæ are longer than the labial; the antennæ are inserted as in *Pinophilus;* the anterior tarsi are strongly dilated in both sexes; and the length of the last joint of the four posterior tarsi is almost equal to that of the four preceding taken together.

2*d*, LONGIPALPI.

In this section the head is also completely exposed, but the labrum is entire, the maxillary palpi nearly as long as the head, with a clavate termination formed by the third joint, the fourth concealed or but slightly visible, and, when apparent, terminating the club in the form of a small point; the preceding much enlarged. These insects dwell chiefly along the shores of rivers, or on banks in the vicinity of water.

In PÆDERUS, Fab. (Plate CCXXII. fig. 15), the antennæ, inserted before the eyes, are filiform, or gradually increase in thickness. In EVÆSTHETUS of Grav. the antennæ are likewise inserted before the eyes, but are hardly longer than the head, and almost entirely moniliform; the body is but slightly elongated, and the head as wide as the thorax. In STENUS,[5] of Lat. (Plate CCXXII. fig. 20), the antennæ are inserted near the margin of the eyes, and are terminated by a triarticulated club. The extremity of the mandibles is forked. The eyes are large.

3*d*, DENTICRURA, Lat.

This section differs from the preceding in the form of the maxillary palpi, which are much shorter than the head, and always consist of four distinct articles; the anterior tibiæ, at least, are dentated or spinous along their exterior side. The last joint of the tarsi, which in most are bent under the tibiæ, is as long as all the preceding joints combined, or longer; and the first or first two are usually so small or so concealed that their total number does not seem to exceed two or three. In several males the forepart of the head, and even the thorax, is armed with horns. The antennæ are inserted before the eyes. With the exception of the *Tachini*, the anterior tarsi are no longer dilated.

In OXYTELUS, Grav. the palpi have an awl-like termination, the antennæ are mostly granose, and gradually enlarged towards the extremity. The tarsi present only

---

[1] *Ann. des Sciences Nat.;* and *Règne Animal*, p. 432.

[2] Mr Stephens arranges his British *Brachelytra* in five families, containing eighty-two genera. How vague, from its extremely comprehensive limits, must have been the original *genus* Staphylinus of Linn., when even our indigenous species present the groundwork of such diversified groups! Perhaps, however, we may be now falling into the opposite extreme.

[3] From ὀξύπορος, *that crosses swiftly.*

[4] *S. dilatatus*, Fab. has been separated from the above on account of its antennæ, which form an elongated serrated club. It is said to feed on caterpillars, which it searches for on trees.

[5] From στενος, *narrow.*

Coleoptera Pentamera.

three distinct articles. In **Ozorius**, Leach, the body is cylindrical, all the tibiæ broadened and dentated, the head as long as it is wide, the thorax almost cordiform. The mentum is large and buckler-shaped. The species come from America and Madagascar. In **Coprophilus**,[1] Lat., the body is flattened, and the antennæ much longer than the head.

4*th*, Depressa, Lat.

In these the head is disengaged or free, as in the preceding, the labrum entire, the maxillary palpi short, and of four articulations; but the tibiæ are simple, or without teeth or exterior spines, and the tarsi exhibit five obvious articulations.

In the two following genera the palpi are filiform. **Omalium**, Grav. Thorax as wide as the elytra, wider than the head, and almost forming a transverse square; the angles, at least the anterior ones, rounded, and frequently exhibiting a raised lateral margin; the antennæ enlarging towards their extremity. **Lesteva**, Lat., *Anthophagus*, Grav. (Plate CCXXII. fig. 22.) Thorax cordiform, narrowed, truncated posteriorly, almost isometrical, as wide as the head, and narrower than the elytra. In the ensuing genera the palpi are subulate. **Micropeplus**,[2] Lat. (Plate CCXXII. figs. 10 and 14.) Antennæ terminating in a solid club, and lodged in fossulæ of the thorax. **Proteinus**, Lat. Antennæ granose, somewhat perfoliate, and larger at the end, but clavate, always exposed, and inserted before the eyes; the thorax is short, and the elytra cover the whole of the abdomen. **Aleochara**, Grav. Antennæ inserted between the eyes, or near their inferior margin, and exposed at the base, with the first three joints obviously longer than the following ones, which are perfoliate, the last elongated and conical; the thorax is nearly oval, or like a square rounded at the angles.

5*th*, Microcephala, Lat.

Head sunk posteriorly into the thorax, nearly up to the eyes, and separated neither by a neck nor visible restriction; the thorax is in the form of a trapezium, and is widened from before backwards. The body is less elongated than in the preceding section, and approaches more to an ellipsis; the head is much narrower, contracted, and projecting forwards, and the mandibles are of moderate size, edentated, and simply curved at the point. The elytra in several cover rather more than the half of the upper surface of the abdomen. Some of the species live on flowers and mushrooms, others on dung.

In **Lomechusa**, Lat., the tibiæ have no spines; the antennæ from the fourth joint form a perfoliaceous club, elongated or fusiform; the palpi are subulate; the antennæ frequently shorter than the head and thorax. In **Tachinus**,[3] Grav. (Plate CCXXII. fig. 23), the tibiæ are spinous, the antennæ composed of pyriform joints, and insensibly enlarging; the palpi are filiform. **Tachyporus**[4] of Grav. (Plate CCXXII. fig. 28) resembles the preceding in the tibiæ and antennæ; but the termination of the palpi is subulate.[5]

FAMILY III.—SERRICORNES, Lat.

In this family of pentamerous Coleoptera, we find only four palpi, as in the preceding family, and those that follow. The elytra cover the abdomen, which character, with certain others, distinguishes the **Serricornes** from the **Brachelytra**.[6] The antennæ, with some exceptions, are equal throughout, or smaller at the extremity, dentated either like a saw or comb, or even fan-like; and in that respect are more developed in the males. The terminal article of the tarsi is often bilobed or bifid. These characters are rarely visible in the ensuing family, that of **Clavicornes**; at which, however, we shall arrive by transition so graduated, that rigorous limits are with difficulty assigned.

Section 1st, Sternoxi,[7] Lat.

Body always of a firm and solid consistence, and generally of an oval or elliptical form; the feet in part contractile; the head sunk vertically into the thorax up to the eyes; and the præsternum or median portion of the thorax elongated, dilated, or advanced as far as beneath the mouth, and usually marked on each side by a groove, in which the antennæ, always short, are lodged, and prolonged posteriorly to a point, which is received by a depression of the anterior extremity of the mesosternum. The anterior legs are distant from the anterior extremity of the thorax. This section is further divisible into two tribes.

Tribe 1st, Buprestides.

In these the posterior projection of the præsternum is flattened, not terminated in a laterally compressed point, and simply received into a depression or emargination of the mesosternum. The mandibles are frequently terminated in an entire point, without fissure or emargination. The posterior angles of the thorax are either not at all or but slightly prolonged. The terminal article of the palpi is generally almost cylindrical, scarcely thicker than the preceding; the others globular or ovoid. Most of the articulations of the tarsi are generally broad or dilated, and furnished with pellets beneath. These insects never leap, a character which distinguishes them decidedly from the *Elaterides*. This tribe corresponds to the old *genus Buprestis*, as constituted by Linnæus,—the *Richard* of Geoffroy;[8] so named by the latter author on account of the extreme richness of their external covering. Even of the European species several are extremely beautiful, and many of the foreign kinds are not only of the largest size for the class of insects, but present a brilliant surface, beset as it were with gold and emeralds, or glittering with an iridescent play of green and azure. The body is in general oval, somewhat lengthened, rather wider and obtuse before, as if truncated, and narrowed behind from the base of the abdomen. The eyes are oval, the thorax short and wide. The scutellum small or unapparent. The extremity of the elytra is frequently dentated. The legs are short.

---

[1] From κοπρος, *dung*, and φιλος, *a lover*.

[2] From μικρος, *small*, and πεπλος, *a covering;* the elytra being so short as to leave a considerable part of the abdomen exposed. This genus is placed in the necrophagous family, *Nitidulidæ*, by Mr Stephens.

[3] From Ταχινος, *swift, active*.

[4] From Ταχυς, *quick*, and πορος, *a passage*.

[5] For the species of this family, see Gravenhorst's *Coleoptera Microptera*, Gyllenhal's *Insecta Succica*, &c. With Mr Duncan's aid, we have described the genera and species of ordinary occurrence near Edinburgh (*Ent. Ed.* pp. 308–388); but, as already mentioned, numerous undescribed *Brachelytra* inhabit Scotland.

[6] In the genus *Atractocerus*, however, the elytra are extremely short. In Proteinus of the preceding family they are, on the other hand, comparatively long; thus showing the tendency to exception in each general rule.

[7] From Στερνον, *sternum*, and οξυς, *pointed*.

[8] "This genus," it has been observed, "furnishes the most beautiful coleopterous insects which can adorn either the domain of nature or the cabinet of the naturalist. Most part of the species are clothed with such brilliant colours, that Geoffroy has thought proper to designate them all under the generic appellation of *Richard*. The origin of this name is as singular as its application is fantastical. It was originally given to the jay, in consequence of the facility with which that bird was taught to pronounce the word." (Griffith's *Animal Kingdom*, *Insecta*, part 2d, p. 356.) Professor Klug has stated that the Berlin Museum possesses not less than five hundred species of the Linnæan genus Buprestis.

All these insects walk very slowly, but fly exceedingly well in dry and sultry weather. When an attempt is made to seize them they drop upon the ground, with a view no doubt to conceal themselves in the subjacent herbage. The abdomen of the female is furnished at its extremity with a coriaceous or horny conical appendage, composed of three pieces (the terminal abdominal rings), and which may be regarded as a kind of ovipositor, by which she deposits her eggs in dry or decayed wood, in which the larvæ dwell. Several of the minor species occur on leaves and flowers; but the greater proportion are found in forests or depots of timber. They sometimes appear suddenly in places where they were never seen before, having been involuntarily transported in foreign timber in the nymph or larva state.

The *Buprestides* are very common in South America and many of the other sultry regions of the earth. They decrease in number as we advance northwards into the temperate climes, and altogether disappear in colder countries. Scarcely a score occur in Britain; and of these we are not aware that even one has yet been found in Scotland.

Genus Buprestis,[1] Lin. Palpi filiform, or slightly enlarged towards the extremity, terminated by an almost cylindrical article. Antennæ of equal thickness throughout, and serrated from the third or fourth joint. Penultimate article of the tarsi deeply notched. Maxillæ bilobed.

These are the characters of the genus Buprestis, as restricted in recent times. Some of the species have no apparent scutellum. Such is *B. fasciculata*, a species from the Cape of Good Hope. It is about an inch long, of a golden or coppery-green, densely punctured, and with little tufts of yellowish or reddish hairs. It sometimes hangs in such abundance on a shrub, as to make it appear all laden with flowers. Others are furnished with a scutellum. Of these we may name *B. gigas* from Cayenne, a species, as its name implies, of the largest size; the thorax cupreous, mingled with brilliant green, and two large spots like burnished steel; the elytra tridentate at the end, cupreous in the centre, bronze-green on the margin, with impressed points and some elevated lines and ridges. Its larva is represented on Plate CCXXII. fig. 19. On the same plate (fig. 18) we have delineated a magnificent species, *B. bicolor*, lately received from Java. It is of a deep-green colour, with a golden lustre, two cream-coloured spots on the elytra, and one on each side of the thorax. It belongs to the genus Catoxantha of Dejean.

Of the other genera of the tribe we shall here name only Trachys, Fab. (Plate CCXXII. fig. 26), Aphanisticus, Lat., and Melasis, Oliv.[2] The last-mentioned genus (probably named from *μελας, black*), conducts naturally to

Tribe 2d, Elaterides.

This numerous tribe corresponds to the undivided genus *Elater* of Linnæus, and differs from the *Buprestides* chiefly in the posterior style of the præsternum, which is prolonged to a sharpish point or spine laterally compressed. On examining the living species, the use of the last-named organ becomes obvious. The legs are very short, and when the creature falls upon its back, which it frequently does while dropping from a plant to the ground, it can only assume its natural position by springing upwards, which it is enabled to do by bringing the projecting point into sudden contact with a groove situated in front of the mesosternum. The sides of the præsternum are also distinguished by a groove, in which the antennæ, pectinated or bearded in several males, are partly lodged. The females have a species of elongated ovipositor, with two lateral pieces pointed at the end, between which is the true oviduct. The tarsi are entire.

The Elaterides occur in flowers, on various plants, and on the ground. We owe to Degeer the description of the larva of one species (*undulatus*). It is long, nearly cylindrical, provided with small antennæ, palpi, and six feet. Its body consisted of twelve scaly segments, of which the posterior was covered by a circular plate, furnished with two blunt points curving inwards; underneath was a large fleshy mammilla, which seemed to serve the office of a foot. The larvæ of *Elater striatus* are said to do much injury, by attacking the roots of wheat. The grub known in this country under the name of wire-worm is an Elater in the early state. It lives under ground for several years, feeding on the roots of grain and vegetables. It is partial to land newly broken up, and does great damage in gardens recently converted from pasture-land. In the year 1813, according to Mr Spence, this larva destroyed the greater proportion of the annuals sown in the botanic garden of Hull. In such cases Sir Joseph Banks recommended that slices of potatoes stuck upon skewers should be buried near the seeds, and examined and cleared of the wire-worms from time to time.

M. Leon Dufour has studied the anatomical structure of several species of this family. In the number, length, and mode of insertion of the hepatic conduits, they show a resemblance to the Carabidæ. The digestive canal is seldom more than once and a half the length of the body. Immediately succeeding an œsophagus, so short as to be included within the region of the head, there is a small smooth conical crop, which appears to have escaped the observation of Ramdhor. The chylific ventricle is bilobed in certain species. This tribe is very extensive both in exotic and European species, and is much more prevalent in temperate and even northern countries than the preceding. The *Elaterides* now consist of numerous genera. Some of the American species are remarkable for the fine phosphoric light which is observed to emanate from them during the evening twilight, and when the shades of night have fallen upon the forests. One of these had the fortune to be transported to Paris under the form of nymph or larva; and having made its escape into the streets after the assumption of the perfect state, it greatly astonished the inhabitants of the Faubourg St Antoine. Most of the genera are recognisable, in a general way, by their narrow, elongated, and somewhat flattish forms. We have above sixty species in Britain, arranged according to the modern views, under not less than twenty genera.

---

[1] From Βους, *an ox*, and πρηστης, *swelling*, in allusion to the supposed injury produced on cattle by an insect anciently named *Buprestis.*

[2] For the species, the reader may consult Olivier, *Coléoptères*, t. ii.; Fabricius, *Systema Eleut.* t. ii.; and Schœnherr's *Synonymia Insectorum.* See also *Règne Animal*, t. iv. p. 446.

The various groups of the *Elaterides* are referred by Latreille to two principal divisions.

1st, Antennæ entirely received into the inferior cavities of the thorax.

In some the antennæ are received on each side into a longitudinal groove, placed directly under the lateral edges of the thorax, and are always filiform, and simply serrated. The joints of the tarsi are always entire, without prolongations, and in the form of a pellet underneath. The thorax is convex or arched, at least on the sides, and dilates towards the posterior angles in the manner of a lobe, pointed or triangular. They approach the *Buprestides.* Here are placed the genera GALBA and EUCNEMIS.

In others the antennæ, sometimes clavate, are received, at least partially, either into the longitudinal grooves of the lateral borders of the præsternum, or into fossettes placed under the posterior angles of the thorax. The tarsi are frequently provided with little pellets, formed by the prolongation of the inferior parts, or the penultimate article is bifid. Here are placed the genus ADOLECERA, Lat. (Plate CCXXII. fig. 29), and others.

2d, Antennæ exterior or exposed.

In the genus CEROPHYTUM, Lat. (Plate CCXXII. fig. 30), the terminal joint of the palpi, especially the maxillary, is much larger than the preceding, and almost securiform. These insects are more particularly distinguished from the following by their tarsi, of which the first four articles are short, triangular, with the penultimate bifid. The antennæ of the males are ramose on the internal side, the base of the third and following articles being prolonged into a widened branch, rounded at the extremity; those of the female are serrated. In the succeeding genera the articles of the tarsi are entire and almost cylindrical. In HEMIRHIPUS, Lat. (Plate CCXXII. fig. 31), the mandibles and labrum are exposed, and the antennæ of the male have a flabelliform termination. The species are foreign to Europe. In ELATER properly so called (Plate CCXXII. fig. 27), the antennæ of the males are simply serrated. Here we place the fire-fly, or *mouche lumineuse* of the French colonists, which during the night diffuses from its thoracic spots a strong and beautiful light, sufficient to enable one to read the smallest print, particularly if several are placed together in a glass vessel. By means of this natural illumination the women of the country (the species is South American) are said to pursue their work, and ladies even use it as an ornament, placing it among their tresses during their evening promenades.[1] M. de la Cordaire, who has studied the habits of these insects in the living state, informed M. Latreille that the principal reservoir of phosphoric matter is placed below, at the junction of the thorax and abdomen.[2] Mr Curtis had the insect alive in London, and has recorded his observations with his accustomed accuracy.[3] In the genus CTENICERA,[4] Lat. the antennæ of the males are pectinated.[5]

We shall conclude by observing that the name of *wire-worm*, bestowed on several larvæ of Elaters, is more specially applicable to the early state of *Cataphagus lineatus*[6] of Stephens. Its history appears to be given in the *Stockholm Transactions* for 1777, by Mr Bierkander. He calls it the *root-worm.* It measures when full grown about seven lines in length. The body is very narrow, of a yellow colour, hard, shining, and composed of twelve segments, on the last of which are two indented dark-coloured specks. The head is brown, the extremity of the jaws black. The anterior segments have six scaly feet. It is said to remain five years in the larva state, from which it issues as an Elater, the *E. segetis* of Bierk. supposed to be synonymous with the *E. lineatus* of Linn. and the insect above named of Stephens. Great damage is often occasioned by the wire-worm to the turnip crops. An instance is recorded by Messrs Kirby and Spence of a field in which it had destroyed one fourth of the crop, and the owner calculated his loss at L.100. He one year sowed a field thrice with turnips, which were twice wholly, and the third time in great part, cut off by this destructive larva.[7]

SECTION 2D, MALACODERMI.[8]

The insects of this section are distinguished from the *Sternoxi* by their bodies being generally, in whole or in part, of a soft or flexible texture. From this character they derive their name. Their head is likewise inclosed posteriorly in the thorax, or at least covered by it at the base; but the præsternum is not dilated or advanced anteriorly in the manner of a chin-cloth (*mentonnière*, Lat.), nor is it usually terminated posteriorly in a point received into a cavity of the mesosternum.[9] The Malacodermi are divided into five tribes.

TRIBE 1ST, CEBRIONITES.

So named from the genus *Cebrio* of Fabricius, with which all the others are connected. The mandibles terminate in a simple or entire point, the palpi are of equal thickness, or more slender towards the extremity. The body is rounded or convex in some, oval or oblong, but curved above, and inclined anteriorly, in others. The thorax is transversal, broader at the base, with the lateral angles sharp, or even prolonged, in many, in the form of a spine. The antennæ are generally longer than the head and thorax. The legs are not contractile. The habits of these insects are unknown. Many are found on plants, in moist places.

In CEBRIO (proper)[10] of Lat. the præsternum terminates posteriorly in a point, received by a groove of the mesosternum. All the joints of the tarsi are entire and without pellets, and the posterior thighs are not larger than the others. The species peculiar to Europe appear in great numbers after heavy rains. Of the ten species enumerated by Dejean, seven occur in Europe, one in Africa, one in Java, and one in North America. In CALLIRHIPIS, Lat. (Plate CCXXII. figs. 32 and 33), the præsternum is not prolonged into a point, the antennæ are closely approximated at the base, inserted on an eminence, and from the third joint, in the males, form a large fan. The terminal joint of the palpi is ovoid, that of the tarsi almost as long as the others united, and presenting between its hooks a little silky and linear appendage. We have represented the head of the species (*C. Dejeanii*), which serves as the type of the genus. It occurs in Java. In RHIPICERA[1] of Lat. and Kirby[2] (Plate CCXXIII. fig. 1), the inferior surface of each of the first four joints of the tarsi presents two membranous and projecting lobes; the last is long. The antennæ are flabelliform in both sexes, and consist of much more than the ordinary number of eleven joints. The articulations are much fewer in those of the females. The genus consists of a few species from North and South America and New Holland. In DASCILLUS, Lat. (*Atopa* of Fab.), the antennæ are simple in both sexes, the first three joints of the tarsi reversed cordiform, without membranous prolongations; the penultimate is deeply bilobed. *D. cervinus* (Curtis, B. E. V. pl. 216), the only British species, occurs rather plentifully in the alpine districts of Scotland. In the remaining Cebrionites the mandibles are small, and project but little, if at all, beyond the labrum. The body is generally soft, and almost hemispherical or ovoid, and the palpi terminate in a point. The posterior legs of several are fitted for leaping. They live on aquatic plants. Such are ELODES[3] of Lat. (*Cyphon*, Fab. Steph.), of which the hind thighs differ but little in thickness from those of the preceding genus (we have seventeen kinds in Britain), and SCYRTES, Lat. of which the species are leapers, with the posterior thighs very large, and the tibiæ terminated by two strong spurs.

[2] *Ibid.* note. See also *Nouvelles Annales du Mus. d'Hist. Nat.* t. ii. p. 66.

[3] *Zoological Journal*, vol. iii. p. 379.

[4] From κτεις, *a comb*, and κεϱας, *a horn.*

[5] For the British genera and species, see the works of Messrs Curtis and Stephens. Such as have been hitherto ascertained to inhabit Scotland are described in *Entomologia Edinensis*, p. 192–9.

[6] From καταφαγω, *I devour.*

[7] The modern genera of Elaterides are far too numerous to admit of being even named in our present article. We refer the reader, in addition to the systematic works of Fabricius, Olivier, and Latreille, to Palisot de Beauvois's *Insectes d'Afrique et d'Amerique*, Dalman's *Analecta Entomologica*, and the beautiful monograph by Count Mannherheim entitled *Eucnemis Insectorum genus.*

[8] From μαλακος, *soft*, and δεϱμα, *skin.*

[9] The *Cebriones* may be said to constitute an exception to this negative character, and thus approximate the Elaterides; but the inferior extremity of the præsternum does not advance under the head.

[10] Aristophanes applies the name Κεϐϱιον to a species of bird.

TRIBE 2D, LAMPYRIDES.

This tribe is distinguished from the preceding by the enlarged termination of the palpi, at least of those of the maxillæ; by their straight, depressed, but slightly convex body; and by the thorax, sometimes semicircular, sometimes nearly square or trapezoidal, projecting over and almost concealing the head. The mandibles are generally small, and terminate in a slender, arcuated, very acute point, generally entire. The penultimate joint of the tarsi is always bilobate, and the terminal hooks have neither dentations nor appendages. The females of some are apterous, or have but short elytra. When seized, most of these insects press their feet and antennæ close to the body, and remain as motionless as if they were dead. Several curve the abdomen underneath. They correspond to the old genus *Lampyris* of Linn., and include some species remarkable for their phosphorescent or luminous qualities.

1st, Antennæ approximated at the base, the head either prolonged anteriorly in the manner of a snout, or for the greater part, or entirely, concealed beneath the thorax. Eyes of the males large and globular. Mouth small.

Here we place the following genera, in all of which the head is exposed:—*1st*, LYCUS,[4] Fab. In this the snout is as long as the preceding portion of the head, or longer, and the antennæ serrated. The elytra are generally dilated, either laterally, or at their posterior extremity, the two sexes (particularly of certain African species) differing greatly in that respect; *2d*, DICTYOPTERA, Lat. (Plate CCXXIII. fig. 2); and, *3d*, OMALISUS,[5] Geoffroy (ibid. fig. 4). The remaining insects of this division are distinguished from the preceding, not only by the want of a snout (it is not apparent even in the last-named genus), by their head, which in the males is almost entirely occupied by the eyes, and much concealed by the square or semicircular thorax—but more particularly by a very remarkable character, either common alike to males or females, or peculiar to the latter sex, viz. the property of phosphorescence. Hence the names of glow-worms, fireflies, &c. bestowed upon the species which form the genus LAMPYRIS properly so called.[6]

In regard to the general history of these insects, we may observe, that the Greeks applied the name of *Lampyris*, and the Latins those of *Noctiluca*, *Luciola*, &c. without any very special reference, to such insects as were observed to shine during the night with a lambent or phosphoric flame. They were long confounded with *Telephorus* and *Malachius* under the genus *Cantharis*. Geoffroy effected their separation from Telephorus, and placed them in the genus *Lycus*, while Linnæus also combined them with that genus and *Pyrochroa*. Fabricius was the first to restrict and define the genus with propriety.[7] The antennæ are short, the articulations cylindrical and compressed. The head is concealed beneath the anterior margin of the thorax, which is semicircular in the indigenous species. The eyes are large. The body rather soft, oblong-oval, much depressed. The abdomen is serrated on its lateral edges. The elytra are coriaceous, and slightly flexible. The legs are compressed and simple. The females are apterous, with the rudiments of elytra at the base of the abdomen. Other characters are minutely detailed by systematic writers, which we need not here enter into. We shall, however, record some observations, both of a general and particular nature, which we were induced to make in consequence of our having kept the common British glow-worm in confinement.[8]

The beautiful light which emanates from this insect constitutes its most interesting and peculiar attribute. If several ancient nations were worshippers of the sun, and regarded "holy light" as a divine effulgence, the offspring of heaven, and the purest of the elements, we need scarcely wonder that in remote times, when natural phenomena were but slightly understood, even the more obscure manifestations of a supposed celestial principle should have excited the wonder and admiration of mankind. We consequently find many exaggerated accounts of the cause and effects of these flying and creeping lights, which, as they do not illustrate the natural history, properly so called, of the insects themselves, we shall leave for the pre-

---

[1] From ϱιπὶς, *a fan*, and κεϱας, *a horn*.

[2] *Linn. Trans.* vol. xii. pl. 21, 3.

[3] From ἕλος, *a marsh*, the species usually frequenting moist places.

[4] From λυκοῶ, *I destroy*.

[5] Perhaps from ομαλος, *flat*.

[6] The word λαμπυϱος occurs in Aristotle, and is derived from λαμπτω, *to shine*, and πυϱ, *fire*. The genus in its undivided state is very extensive, containing not fewer than sixty species. We observe, however, that in the last edition of Dejean's Catalogue, so many divisions have taken place, that the genus Lampyris, properly so called, is now made to consist of only *nine* species. It is very poorly represented in Britain, and indeed produces but few European examples. If, as Mr Stephens supposes, *L. splendidula* has been erroneously introduced into the British Fauna, then *L. noctiluca*, Linn., may be regarded as the sole indigenous species. Some Brazilian species, in which the antennæ of the males consist of more than eleven joints, formed like the laminæ of a feather, constitute the genus *Amydetes* of Hoffmansegg. Others, also peculiar to South America, and of which the antennæ consist of only eleven joints, form the genus *Phengodes* of that author. (Illiger's *Mag.* vi. p. 342.)

[7] For representations of the glow-worm (*L. noctiluca*), see Plate CCXXIII. Fig. 5 is the winged male; fig. 6 the wingless female; fig. 7 the larva; fig. 10 represents a large and remarkable species, the *Lampyris Savignii* of Kirby.

[8] We here in part avail ourselves of what we have already stated in the *Entomologia Edinensis*, p. 202–7.

Coleoptera Pentamera.

sent unrecorded. But the actual phenomena are extremely interesting, on account both of their singularity and beauty, and, without the aid of fiction, are well deserving the attention of the poet and philosopher. Huet, bishop of Avranches, an eminent scholar, composed a poem, entitled *Lampyris;* and the masterly genius of Wordsworth, which draws so much that is new and beautiful from the observance of common things, has not failed to immortalize the radiance of the "earth-born star." "And if," say Messrs Kirby and Spence, or one or other of these authors, while speaking of the British glow-worm, "living like me in a district where it is rarely met with, the first time you saw this insect chanced to be, as it was in my case, one of those delightful evenings which an English summer seldom yields, when not a breeze disturbs the balmy air, and hundreds of these radiant worms, studding their mossy couch with mild effulgence, were presented to your wondering eye in the course of a quarter of a mile,—you could not help associating with the name of glow-worm the most pleasing recollections. No wonder that an insect which chiefly exhibits itself on occasions so interesting, and whose economy is so remarkable, should have afforded exquisite images and illustrations to those poets who have cultivated natural history."[1] However beautiful the effect produced by our own species, and by the fire-flies (*L. italica*), which are still more abundant over Italy and the rest of the south of Europe, their splendour, according to Humboldt, cannot be compared in richness to those innumerable scattered and moving lights that embellish the nights of the torrid zone, and seem to repeat on earth, along the vast extent of the savannahs, the spectacle of the starry vault of heaven. These, however, belong to a different tribe of insects (Elaterides), which resemble the glow-worm merely in their luminous properties; yet we cannot resist quoting the beautiful lines by Mr Southey, in which he describes their first effect on the earliest visitors of the new world.

> .... Sorrowing we beheld
> The night come on; but soon did night display
> More wonders than it veiled; innumerous tribes
> From the wood-cover swarm'd, and darkness made
> Their beauties visible: one while they streamed
> A bright blue radiance upon flowers that closed
> Their gorgeous colours from the eye of day;
> Now motionless and dark, eluded search,
> Self-shrouded; and anon, starring the sky,
> Rose like a shower of fire.[2]

The glow-worm is now a very rare insect in the neighbourhood of Edinburgh. Mr Neill informs us that it formerly occurred between the city and the village of Canonmills; but we have not heard of its having been found there or elsewhere around our immediate suburbs for many years. Dr David Ritchie has observed it occasionally near Pathhead, and Professor Wallace has met with it in Fife. Professor Wilson informs us that he once saw it on the Queensferry road, near Comely Bank. We have ourselves taken it by Loch Lomond side, and elsewhere in Scotland. It abounds in the north of England. We once received some living specimens early in July from Borthwick, about twelve miles from Edinburgh. They laid eggs a few days after their arrival, on the sides of a glass vessel. The parents soon after died, probably from being kept in too confined a space; but the young larvæ were hatched in a few weeks, and by the end of September they measured about the third of an inch in length. These larvæ bear a strong resemblance to the female perfect insect. The body is composed of twelve segments, of which the central are the largest. The three first segments bear each a pair of feet, and the caudal segments are slightly retractile within each other; and when the insect walks, which it does very leisurely, it bends its tail beneath it in such a way as to assist or support it in its progress. The head is very small, and is also retractile, and is usually withdrawn whenever the insect is alarmed or disturbed. These little creatures throve well in captivity. They were kept on a piece of moist mossy turf, which was frequently renewed; but whether they sustained themselves on the dewy herbage, or by means of the minute animal substances which it contained, it was not for a time very easy to discover. The curved and extended form of the little jaws would in the first place induce one to suppose that they were carnivorous. Olivier, however, observes, in his description of the larva of the glow-worm, "elle vie cependant sur de la terre fraîche, avec de l'herbe et des feuilles des différentes plantes; mais l'on a remarqué qu'elle devient foible et languissante, quand on la laisse manquer de terre humide. Elle est très-pacifique, et paroit craintive."[3] Fresh earth, or the moisture which arises from it, certainly seems necessary to their welfare, for we noticed that, when their turf became dry, and a slice of fresh apple or potato was introduced, they immediately settled on it, and inserted their heads as if drinking. We, however, soon after detected one with its jaws fixed in the head of a minute snail, which it appeared to be devouring, its own head being inserted into the aperture of the shell.

This observation appeared the more interesting, in as far as it served to connect those insects, by means of their habits, with that singular species the *Drilus flavescens*, which is known to feed voraciously on the *Helix nemoralis*, and the female of which was described by Mielzinski as the type of a distinct genus, under the name of *Cochleoctonus*. This latter insect is parasitical on the body of the helix, in the shell of which it dwells and undergoes its metamorphoses.

While engaged in the observance of these glow-worms, we met with a notice, in the *Annales des Sciences*, by a French gentleman of Rouen, on the same subject. In it we have ample proof of the carnivorous propensities of the creatures in question. He placed a great number of the larvæ in a vessel with fresh earth, and supplied them with various kinds of leaves. They soon however became extremely feeble, and remained so for several weeks, when he happened to put a dead slug in their jar, of which the young glow-worms were no sooner aware than they greedily seized upon it with their arched and sharp-pointed mandibles. On the ensuing day they were found to have eaten their way so far into the slug, that nothing but their tails was visible. They were perceived however occasionally to quit their prey and walk about upon the moist earth. The French naturalist was curious to observe how they would proceed with a living snail, and he therefore introduced one into his colony of insects. The animal soon began to crawl about its new domicile, but it no sooner came upon the path of a glow-worm than it was seized by the latter immediately beneath the mouth, and with such force and tenacity that it drew itself suddenly into its shell, and of course dragged its enemy along with it. The glow-worm however immediately disengaged its hold, and struggled back to the mouth of the shell, on the back of which it soon mounted, thus keeping the snail in a state of siege. Whenever it protruded even the point of its horns it was instantly seized, bitten, and obliged to withdraw within its fortress. The larva being soon joined by a companion, the two attacked the unfortunate snail, and

---

[1] *Introduction to Entomology*, vol. ii. p. 410.

[2] *Madoc.*

[3] *Entomologie*, t. ii. No. 28, p. 7.

after a continued combat of several hours, they put it to death, and by next morning it was not only slain, but eaten. These and similar experiments were made from the month of November to the month of June, after which the larvæ were observed to undergo their transformations. They occupied about a week in assuming the state of nymph—they continued in that state eight days longer—and then appeared in the form of the perfect insect. When about to assume the nympha state, the skin of the upper and anterior portion of the body cracks and opens, or a lateral division takes place on either side, so as to separate the skin of the upper from that of the under portion. By alternate elongations and contractions they then work their way forwards, and contrive to effect their liberation in a few minutes from their old attire. The nymph is larger than the larva, though not quite so long. Its colour is at first pale yellow, with two reddish spots on the posterior and lateral portion of each segment of the abdomen, as well as on the posterior angles of the thorax. It wants the large acute mandibles of the larva; its antennæ are very obvious, and consist of eleven articulations. The tarsi are likewise distinctly composed each of five articulations. The last rings of the abdomen are very brilliant, especially when the insect is handled; and it was noted as remarkable that the whole body partook, though with less intensity, of that phosphoric splendour which in the perfect insect characterizes only the terminal segments of the abdomen. Before the termination of the eight days which are passed in the nympha state, all the more delicate colours had disappeared, and were finally converted into those duller hues which distinguish the insect in its matured condition. As soon as it has disengaged itself from the slough of the larva, it bends its body into an arch or semicircle, and is then a genuine nymph, although it still continues to move its head, and even its limbs and antennæ. In this intermediate condition its general form has undergone no great change, but the head, feet, and antennæ are considerably altered, and seem enlarged or swollen. At first the body manifests a slow and heavy movement, which ere long ceases, and the antennæ and feet are then applied more closely to the sides of the body. The only signs of life now consist in a movement of the abdomen, which is bent into an arch, or occasionally moved from side to side. The body is shorter than that of the larva, the head is bent beneath the first segment or thorax, the antennæ consist of numerous articulations, and the caudal segment of the body, instead of being terminated by a couple of points, is now surrounded by eight of those points, in the centre of which are two fleshy tubercles, placed in a slight depression. Olivier had previously informed us that the nymph, after quitting the skin of the larva, shone with a very lively and brilliant light of a beautiful green colour, which became more splendid for a time when the vessel which contained it was moved, and disappeared again, as if by some voluntary action of the animal, even in the nympha state, in which the vital and instinctive powers are usually almost in a state of suspension. According to Degeer, the larva is also luminous. We did not however observe any manifestation of that faculty in those in our keeping.

It has been a frequent subject of inquiry to ascertain the purposes which the light is intended to serve. In the perfect state the female continues wingless, while the male has become a swift-flying insect; and this has led to the supposition that the lambent flame, which is always most conspicuous in the female, is intended as a "nuptial lamp," to guide the male to her society. In this case, however, we do not so clearly see the use of it in the larva and nympha states, unless, to be sure, as a preparatory process for the formation of the animal phosphorus. Although many insects discover each other merely by the sense of smell, the fact seems nearly certain that the male or winged glow-worm ascertains his mate by aid of her luminous property; for it is a well-known and successful entomological device to place a female in a conspicuous position, and watch by her side, with a view to entrap the rarer or less visible males, which ere long make their appearance. Olivier has frequently caught the males by holding a female on the palm of his hand,—which makes it the more singular that he did not perceive the two luminous points which the former bears on the last segment of the abdomen,—"Je n'ai pas encore m'assurer, il est vrai, si le mâle de notre espèce commune a la propriété de luire." We may add, that the eggs are also beautifully luminous for some time after they are laid.

Dufour has examined the anatomical structure of the female glow-worm. The alimentary canal measures about twice the length of the body. The œsophagus is so short as to be nearly imperceptible. It dilates immediately into a short crop. The chylific ventricle is separated from the crop by a valvular contraction. It is long, smooth, that is, unprovided with papillæ, but pursed and cylindrical in its two anterior thirds, and intestiform in the remainder. The small intestine is very short.[1]

The matter from which the luminous property of the glow-worm results has been the subject of frequent experiment and observation. It is obviously under the control of the insect, which, when approached, may frequently be observed to diminish or put out its light.[2]

In the perfect female the luminous matter occupies chiefly the inferior part of the three last annuli of the abdomen. These differ from the rest in colour, and are usually of a yellow hue, especially on the under side. The light diffused is more or less intense, according to circumstances. The insect lives for a considerable time in a vacuum, and in various gases; but in nitrous acid, muriatic and sulphurous gases, it soon expires. When placed in hydrogen gas it has sometimes been observed to produce detonation. When the luminous portion of the body of a glow-worm is cut off, the insect continues to live, and the separated segments retain their phosphoric nature, and are luminous for some time, whether placed in vacuum, exposed to the air, or submitted to the action of different gases. By what means the living insect is able to shroud itself in darkness, and then suddenly to clothe itself as it were in a mantle of radiant light, is a subject beyond our power of investigation; but when dried the phosphorescence seems to depend on a certain degree of softness or humidity; for when apparently quite extinct, it may be reproduced by pressure, and the application of a little moisture. In the living state, however, although immersion in warm water produces a brilliant light, the application of cold water tends to its speedy extinction.

The next peculiarity in the history of the glow-worm consists in the change of its habits in regard to food, which takes place on its attaining maturity. From an insect of a predaceous nature, greedy of animal juices, it becomes entirely herbivorous, not much addicted indeed to food of any kind, but still confining itself, when it does indulge in eating, to the tender leaves of plants. It is this circumstance which has no doubt led to so much contrariety of opinion on the part of entomological writers regarding its natural disposition. Most observers having attended to it chiefly after it had undergone its transformations, they naturally, and so far correctly, concluded that it was a herbivorous insect. Had they watched its progress from the egg they would have come to another conclusion, at least in regard to its earlier condition. This alteration in the habits of these creatures is in fact by no means unexampled, either among other genera of the same class, or among the more distantly related reptile tribes. The most familiar instance among the latter is the common frog, which in the early state of tadpole is herbivorous, while under the perfect form it preys on flies and other insects. In this case, to be sure, the order of change is inverted, the alteration being from a herbivorous to a carnivorous diet; while the contrary takes place in the glow-worm. But the analogy is more strictly maintained in the case of those aquatic beetles which form the family of *Helophoridæ*, which in the larva state are carnivorous, but become herbivorous after assuming their final transformation. The same singularity is also illustrated by many dipterous flies, which, born and bred amid the putrid moisture of animal remains, no sooner become winged insects, than they seek a purer diet in the nectarous juices of fruits and flowers.

---

[1] *Ann. des Sciences Nat.* t. iii. p. 225.

[2] On this curious subject, however, we beg to refer the reader to the writings of Beckerheim (*Ann. de Chimie*, t. iv. p. 19), Caradori, and Treviranus, among foreign authors,—and to those of Mr Macartney (*Phil. Trans.* 1810), and Kirby and Spence (vol. ii. p. 423), among ourselves.

In relation to the glow-worm, the observation is of more practical interest, because the appearance of the insect among our lawns and shrubberies is so extremely ornamental during the summer nights, that many have tried to import it to districts where it does not naturally occur. They have failed, in consequence of endeavouring to rear the young on vegetable food. Moist herbage, or a supply of damp earth, seems almost indispensable; but, in addition to these, their box must contain some minute testacea, such as the young of the ordinary species of the genus Helix. Perhaps the best plan is to hatch the eggs, and then place the young at liberty under an old hedge as soon as they have begun to eat freely.

2*d*, Antennæ decidedly remote at their base; head neither prolonged nor narrowed anteriorly in the form of a snout; the eyes of ordinary size in both sexes.

In genus DRYLUS, Oliv. (Plate CCXXIII. figs. 8, 9, and 12), the males are winged, and the inner side of the antennæ, from the fourth joint, is prolonged like the tooth of a comb. Those of the female are shorter, or somewhat perfoliaceous, and slightly serrated. The maxillary palpi in both sexes are thicker towards the extremity, and terminate in a point. There is a tooth on the internal side of the mandibles. The *D. flavescens* (see figs. last referred to) feeds, while in the larva state, on the *Helix nemoralis* of Linn. in the shell of which it dwells and undergoes its metamorphosis. It was on this account described by Comte Mielzinsky under the name of *Cochleoctonus*. Its history, and that of the other species, are now well known.[1]

All the remaining genera of this second division of the *Lampyrides* are winged in both sexes, and the maxillary palpi are not much longer than the labial. They correspond to the family *Telephoridæ* of English naturalists, and are composed chiefly of the species placed by Linnæus under the genus *Cantharis*. Schœffer and Degeer reserve that name to the species used in medicine, and apply the term Telephorus (probably from *θελος φορεω*, *I carry death*) to the remainder. The true Cantharidæ, therefore, are constituted by the genus Meloe, and the well-known blister-fly *C. vesicatoria*, &c.

In the genus TELEPHORUS (Plate CCXXIII. fig. 11) the palpi are terminated by a securiform article, and the thorax offers no lateral emarginations. Their bodies are long, narrow, depressed, and of a soft or somewhat flexible consistence. These insects abound in meadows during the summer season, on umbelliferous and other plants. The larvæ are characterized by a flat scaly head, furnished with two strong teeth, a pair of small antennæ, and four palpi. Their bodies are flattish beneath, divided into twelve rings resembling those of caterpillars, and covered by a membranous skin, which is soft to the touch. The general colour of these larvæ is a deep velvety black, except the front of the head, which is shining. The antennæ, palpi, and feet are of a reddish or yellowish brown. They dwell in moist earth. Olivier was of opinion that they fed on roots, but the laborious and accurate Degeer asserts that they voraciously devour a great variety of insect prey. That of *Telephorus fuscus* was observed to change into the nympha state towards the end of May. It buried itself in the earth, but presented no appearance of cocoon. The nympha was about six lines in length, with the body somewhat arched, and of a pale-reddish white. The perfect insect was developed in the month of June. Even in the last-named state, in which so many species are chiefly occupied in the indulgence of other propensities, the Telephori, according to Degeer, continue their accustomed appetite. He has observed a female drag a male to the ground, turn him on his back, and suck out his entrails; so that, as among the spider tribes, considerable caution is necessary on the part of an inexperienced suitor while making his advances. Mr Curtis has frequently seen Telephori with other insects in their mouths. He once observed *T. lividus* eating an ichneumon, and he took another of the same species with an Empis in its mouth. *T. fuscus* is known to prey upon its own species. There are above thirty different kinds of this genus in Britain. Dejean, under the Linnæan name of *Cantharis*, enumerates 132 species. Whatever we know of the anatomy of these creatures accords with their apparent dispositions. Dufour has ascertained that their digestive canal is absolutely straight. Their biliary vessels are four in number, in which character, as well as in that of their generative system, they present a resemblance to the genus Lycus.

One of the most remarkable incidents in the history of the Telephori is the frequency with which, in some continental countries, the species are carried into the air in great quantities by violent winds, and unexpectedly deposited in distant regions,—thus giving rise to what are called *insect showers*. Sweden and Hungary have been most productive of such phenomena. One of the most ornamental of the British species, and the only one we shall here describe, is *T. cyaneus* of Curtis. The head is black and shining, but rufous before the eyes; the thorax and abdomen are likewise rufous, the elytra are deep blue, the legs black. This insect is pretty widely, though sparingly, distributed over the southern and central counties of Scotland, and the north of England. We have specimens from the Edinburgh district, from Kinordy in Forfarshire, from Dollar in Clackmannanshire, and from Dumfries and Roxburgh shires.

The genus SILIS of Megerle differs from the preceding chiefly in having an emargination posteriorly on each side of the thorax. In MALTHINUS of Lat. (Plate CCXXIII. fig. 14) the palpi are terminated by an ovoid joint; the head is narrow behind; and the elytra, in several species, are shorter than the abdomen.

---

[1] See *Annales des Sciences Nat.* Jan. Juil. Aout, 1824; and *le Bulletin de la Soc. Phil.* for April of the same year.

Tribe 3d, Melyrides.

Here we find the palpi generally short and filiform; the mandibles emarginated at the point; the body usually narrow and elongated; the head only covered at base by a flat or but slightly convex thorax, generally square, or elongated and quadrilateral; the joints of the tarsi entire, and the terminal hooks unidentated or bordered with a membrane. The antennæ are usually serrated, and even pectinated, in the males of several species. Most of these insects are of active habits. They occur on the leaves and flowers of plants.

In Malachius[1] of Fab. (Plate CCXXIII. fig. 13), there is a retractile and dilatable vesicle under each anterior angle of the thorax, and on each side of the base of the abdomen. Most of the species are adorned by ornamental and contrasted colours. The habits of the larvæ are but obscurely known. Olivier presumes that many of them live in wood, because he has frequently found the perfect insect in timber-yards, as if newly escaped from the nympha state. This is an extensive genus, and may be regarded as characteristic of temperate climes, although a few occur in Africa and the East Indies. Mr Stephens enumerates seventeen British species. Comte Dejean's collection contains 104 in all. Among the Melyrides with filiform antennæ, but of which the thorax and abdomen are unfurnished with retractile vesicles, Latreille places the genus Dasytes[2] of Paykul. The antennæ are at least as long as the head and thorax; and the body is generally narrow and elongated, sometimes linear. We have figured the male of *D. ater* (Plate CCXXIII. fig. 15). In Melyris properly so called (Plate CCXXIII. fig. 16), the antennæ are shorter than the head and thorax, insensibly enlarged, but without forming a club, as in *Lygia*. Their joints are also less dilated laterally, and are almost isometrical. The thorax is less convex.

In other Melyrides, such as Pelocophorus of Dej. the maxillary palpi are terminated by a larger and securiform article, a character which, with certain others, approximates them to the ensuing tribe. Dejean at one time placed them among the *tetramerous* species.

Tribe 4th, Clerii.

Distinguished by at least two of the palpi being projecting and clavate. The mandibles are dentated. The penultimate joint of the tarsi is bilobate, the first very short or but slightly visible in several. The antennæ vary, being in some nearly filiform and serrated, in others insensibly enlarged towards the extremity. The body is usually cylindrical, the head and thorax narrower than the abdomen, and the eyes emarginate. Most of these insects occur on flowers, some of them on the trunks of trees or in dry timber. The larvæ are regarded as carnivorous.

Of some the tarsi, viewed from above or from beneath, distinctly exhibit five joints. Such is the genus Tillus[3] of Olivier, in which the mandibles are cleft or bidentated at the extremity; the antennæ sometimes serrated, from the fourth joint to the tenth inclusively, with the last ovoid, sometimes terminating suddenly from the sixth in a serrated club. The terminal joint of the labial palpi is very large and securiform; the head short and rounded, and the third and fourth joints of the tarsi dilated in the form of a reversed triangle.

Of others the tarsi, when viewed from above, appear to consist of only four joints, the first being extremely short, or concealed beneath the second. Such is the genus Clerus[4] properly so called (Plate CCXXIII. fig. 17), in which the maxillary palpi are terminated by a compressed joint in the form of a reversed triangle, the last of the labial palpi, which are larger than the others, being securiform. The club of the antennæ is hardly longer than wide, and is composed of crowded joints; the third is longer than the second. The maxillæ terminate in a fringed and projecting lobe. The thorax is depressed anteriorly. The species, in the perfect state, occur on flowers. Their larvæ feed on those of certain bees. Dufour has described their internal structure. The crop is so short as to be almost entirely contained within the head. In Necrobia,[5] Lat. (Plate CCXXIII. fig. 19), the four palpi are terminated by an elongated, compressed, triangular joint of the same size; the second and third joints of the antennæ are almost equal, and the terminal club is elongated, and with looser articles. These insects occur chiefly in spring. They are said to live on carrion, and are richly adorned for such foul feeders. Deep blue is their prevailing colour. There are four species in Britain, of which we have as yet found only two in Scotland, viz. *N. ruficollis*, of a greenish blue, the thorax, base of the elytra, and legs rufous,—*N. violacea*, of a bright blue, shining yet pubescent, the antennæ and legs black. If the geographical notices which we have collected of the former species be correct, its distribution must be very extensive. It seems to occur both in Africa and the East Indies,—a wide circuit for an insect which we have taken behind the glass-works at Leith. "Insectum mihi carissimum," says Latreille, "illis enim infelicissimis temporibus quibus calamitatum omnium pondere obruta Gallia trepidanter gemebat, amicissime auxiliantibus Bory de Saint Vincent, Dargelas, Burdigalensibus, posteriori maxime, hoc animalculum mihi libertatis salutisque occasio miranda evasit."[6]

Tribe 5th, Ptiniores, Lat.

This tribe, consisting of the genus Ptinus of Linnæus, and of some others nearly allied, possesses a body of a tolerably firm consistence, in some cases almost ovoid or oval, and at others nearly cylindrical, but generally short, and rounded at either end. The head is nearly globular or orbicular, and is received almost entirely into a strongly arched or rounded thorax, resembling a hood. The antennæ of some are filiform, or diminished towards the termination, and are simple, flabelliform, pectinated, or serrated; of others they are terminated suddenly by three larger and longer joints. The mandibles are short, thick, and dentated beneath the point. The palpi are very short, and terminated by a larger article, almost ovoid, or like a reversed triangle. The tibiæ are not dentated, and the spurs at the extremities are very small. These insects are all of small size, exhibit little variety in their colouring, which is usually dark or sombre, and when touched they counterfeit death. Their motions are slow, and such as are winged seldom take to flight. In the larva state they are extremely destructive in museums.

In the genus Ptinus (Plate CCXXIII. fig. 18) properly so called, the antennæ are as long as the body, and inserted between the eyes, which are somewhat protuberant. The body is oblong. In the genus Ptilinus, Fab. (ibid. fig. 20), the antennæ, inserted before the eyes, are shorter than the body, and are pectinated or plumose from the third joint in the males[1]—serrated in the females. They inhabit old wood, in which they perforate deep round holes. In ANOBIUM, Fab. the antennæ are terminated by three larger or longer joints, the terminal one being ovate. The name of *Byrrhus*, originally bestowed upon the insects of the last-named genus by Geoffroy, was transferred by Linnæus to a very different group. His genus *Ptinus* included both *Ptilinus* and *Anobium*. Fabricius was the institutor of the genus Anobium, so called from *αναϐιον*, *resuscitated*,—the species being characterized, in common with most of their congeners, by their frequent simulation of death, and their re-assumption of activity as soon as the threatened danger is removed. In this instinctive mode of preservation Olivier accuses them of exhibiting an invincible obstinacy. “Ils se laissent entièrement bruler sans donner aucun signe de vie.” The larvæ of these insects are extremely injurious to old furniture, in which they perforate numerous round holes. Hence the genus is named vrillette by the French, from *vrille*, a gimlet. In the larva state they resemble small, white, soft worms, with six short minute feet. The head is scaly, and is terminated by two maxillæ in the form of strong cutting pincers, with which they gnaw the wood into the finest sawdust. When about to change into the nympha state, they line the bottom of their little cells with a few silken threads. Other species feed on flour, bread, sealing-wafers, &c. where they form grooves or galleries, according to the thickness of their working materials. The superstitious fancy of the *death-watch* has arisen partly from an insect of this genus, the *An. tessellatum*. It is supposed, however, to share this mysterious calling with the *Termes pulsatorium* of Linnæus, and probably with several others. According to Dr Shaw, it is in the advanced state of spring that the former of these insects commences its mysterious pulsations, which, he asserts, is nothing more than the signal-call of the sexes. The number of distinct strokes is generally from seven to eleven, and these are occasioned merely by its beating with its head with considerable force and quickness against the plane of its position. Where the insects are numerous, as is not unfrequently the case in old houses, these sounds may be heard during the whole day, especially in warm weather. The sound greatly resembles a moderate tapping on a table with the finger nail, and indeed by that simple process they may be induced to beat in reply when not otherwise inclined so to do. “He that could eradicate this error,” says the quaint Sir Thomas Brown, in allusion to the death-tick, “from the minds of the people, would save from many a cold sweat the meticulous heads of nurses and grandmothers.”[2] One of the most common species of the genus is *Anobium striatum*, of a somewhat pitchy-brown colour, the thorax obsoletely grooved, and produced towards the base into an elevated triangular ridge. This little timber borer, which is the *A. pertinax* of Fabricius, has been long famous for a most *pertinaceous* simulation of death. “All that has been related of the heroic constancy of American savages when taken and tortured by their enemies, scarcely comes up to that which these little creatures exhibit. You may maim them, pull them limb from limb, roast them alive over a slow fire,[3] but you will not gain your end; not a joint will they move, nor show by the least symptom that they suffer pain. Do not think, however, that I ever tried these experiments upon them myself, or that I recommend you to do the same.”[4] This species was observed by Latreille to produce the sound called the *death-tick*, by striking its mandibles upon wood. On this occasion it was immediately answered from within by a precisely similar sound. We took a very rare British species, *A. abietis*, Fab. many years ago in a fir-wood near Edinburgh. *A. erythropum* of Leach is also stated by Mr Stephens to have been taken at Ravelston.

[4] The word κληρος is applied by Aristotle to an insect which inhabits hives.

[5] From νεκρος, *curcass*, and βιος, *life.*

[6] *Genera Crust. et Insect.*

SECTION 3D, XYLOTROGI, Lat.

This final section of the SERRICORNES is distinguished from the two preceding by the freedom of the head, which is completely exposed and separated from the thorax by a strangulation or species of neck. It is composed entirely of the genus *Lymexylon* of Fab. as subdivided by recent writers.

In ATRACTOCERUS of Palisot de Beauvois, the elytra are extremely short, and in the form of little scales; the antennæ are compressed and almost fusiform; the thorax is square, the abdomen depressed. This limited and very anomalous-looking genus (it has the aspect of a *Staphylinus*) has representatives in Guinea, Brazil, and Java. A species is likewise known to occur in amber. In LYMEXYLON,[5] Fab. the elytra are as long or little shorter than the abdomen, the antennæ are simple, slightly if at all compressed, and almost moniliform. The thorax is nearly cylindrical. The *L. navale*, Fab. (of which *L. flavipes* of the same author is the male), is a small narrow insect of about half an inch in length, of a pale fulvous colour; the head, exterior margin, and extremity of the elytra black,—the latter colour more predominant in the males. This species is extremely common in the oak forests of the north of Europe, although unknown in Britain, and rare in the vicinity of Paris. Its larva is so long and slender as almost to resemble a *Filaria*. It multiplied so prodigiously some years ago in the dock-yards at Toulon, as to cause the destruction of great quantities of timber.[6]

FAMILY IV.—CLAVICORNES, LAT.

In this family, as in the preceding, we find four palpi, and elytra covering the upper surface of the abdomen, or its greater portion; but the antennæ are almost always thicker at the extremity, which frequently forms even a perfoliaceous or a solid club; they are longer than the maxillary palpi, and their base is exposed or scarcely covered. The legs are not fitted for swimming, and the joints of the tarsi, at least of the posterior ones, are usually entire. In the larva state they feed on animal matter. Latreille divides the tribe into two sections.

SECTION 1ST. Antennæ always composed of eleven joints, longer than the head, not forming from the third articulation a fusiform or nearly cylindrical club; the second joint not dilated in the form of an auricle. The terminal joints of the tarsi, as well as its hooks, of moderate length, or small. All the genera of this section are terrestrial. It comprises several tribes.

TRIBE 1ST, PALPATORES.

These, in a natural series, should be placed near the Pselaphii and Brachelytrous genera. Their antennæ are at least as long as the head, are slightly enlarged towards the extremity, or are nearly filiform; their first two joints are longer than those that follow. The head is distinguished from the thorax by an ovoid strangulation. The maxillary palpi project, and are long and inflated at the extremity. The abdomen is large, oval or ovoid, and laterally embraced by the elytra. The legs are elongated, the thighs clavate, the joints of the tarsi entire. These insects are found on the ground beneath stones and other substances. They form a single genus, divided by some writers into MASTIGUS and SCYDMÆNUS. The latter frequent moist places.

---

[1] The generic name is no doubt derived from πτιλον, *a feather*,—in reference to the form of the antennæ.

[2] *Pseudodoxia Epidemica.*

[5] From λυμη, *destruction*, and ξυλον, *wood.*

[6] *Règne Animal*, t. iv. p. 369.

In all the following Clavicornes the head is generally sunk in the thorax, and the maxillary palpi are never at the same time advanced and club-shaped.

TRIBE 2D, HISTEROIDES.

This tribe is composed of the great genus *Hister* of Linnæus. The four posterior legs are more widely separated from each other at their origin than the anterior pair. The legs are contractile, and the exterior tibiæ dentated or spinous. The antennæ are always bent or *elbowed* (geniculate), and terminated in a solid mass, or composed of close-set articulations. The body is of a very solid consistence, and the elytra so hard that even the pin of the entomologist is with difficulty made to enter, and the præsternum is often dilated in front, and the elytra truncated. The mandibles are strong, and not unfrequently unequal as to size. The palpi are almost filiform, or slightly enlarged at their extremity, and terminated by an oval or ovoid article. In respect to their habits, the dentation of their tibiæ, and some other circumstances, these insects seem to exhibit an approach to the coprophagous LAMELLICORNES; but both Dufour[1] and Latreille[2] are of opinion that well-founded anatomical considerations connect them with the SILPHÆ. In the species (*H. sinuatus*) dissected by the former author, the digestive canal was found to be four or five times as long as the body. The œsophagus is extremely short; the oblong enlargement which immediately succeeds it exhibits throughout its parictes some brownish lines, which seem to indicate the existence of interior appendages proper for trituration; and if so, such enlargement may be regarded as the gizzard. The chylific ventricle is very long, twisted on itself, and beset with pointed and projecting papillæ. The hepatic vessels have six distinct insertions around the chylific ventricle.[3]

These insects feed on putrid and stercoraceous substances, decaying vegetables, &c. and some dwell beneath the bark of trees. Their movements are slow, their colour blackish, frequently with a tinge of bronze. Such of the larvæ as are known to naturalists affect the same food as the perfect insect. Their form, however, is different, being almost linear, depressed, smooth, soft, and of a yellowish white, with the exception of the head and first segment, of which the skin is scaly and of a brown or reddish colour. These larvæ have six short legs, and are terminated by a pair of articulated appendages, and an anal prolongation or tube. The scaly shield of the first segment is longitudinally channelled.

In some the tibiæ, at least the anterior ones, are triangular and dentated, and the antennæ always free and exposed, the body square, and slightly if at all inflated. Such is the genus HOLEPTA of Paykul, in which the body is much depressed, the mentum deeply emarginate, and the palpi formed of almost cylindrical joints. The species dwell beneath the bark of trees. In HISTER[4] properly so called (Plate CCXXIII. fig. 22), the præsternum projects beyond the mouth, and the palpi are composed of joints, the last excepted, rather in the form of a reversed cone than cylindrical.[5]

TRIBE 3D, SILPHALES.

In these and the remaining CLAVICORNES the legs are inserted at an equal distance from each other, and, with the exception of the eighth tribe (BYRRHII), the legs are not contractile, or at most the tarsi only can be bent upon the tibiæ, the mandibles are generally salient and flattened or not thick, and the præsternum is more dilated anteriorly.

In the SILPHALES we find five distinct joints in all the tarsi, and the mandibles terminate in an entire point without fissure or emargination.[6] The antennæ terminate in a club which is generally perfoliated, and composed of four or five articulations. The internal side of the maxillæ in some is furnished with a horny tooth. The anterior tarsi are frequently dilated in the males, and the exterior margin of the elytra of the greater number is marked by a groove with an obvious border. This tribe is composed of the genus SILPHA of Linnæus.

In the genus NECROPHORUS, Fab. so named from νεκρος, *a carcass*, and φορεω, *I carry* (Plate CCXXIII. fig. 21), the antennæ, scarcely longer than the head, terminate abruptly in an almost globular club of four joints, the first of which is long, and the second much shorter than the third. The body forms nearly a parallelopiped; the thorax is widest anteriorly; all the tibiæ are strong, widened at the extremity, and terminated by strong spurs; the elytra are truncated at right angles. The maxillæ are destitute of a corneous claw.

This important and well-marked genus was first defined by Fabricius. Linnæus had placed the species of which it is composed with the Silphæ, while Scopoli and Geoffroy combined them with the genus Dermestes. The most marked peculiarity in their manners consists in their habit of interring small animals, such as mice and moles, for the purpose of depositing their eggs in their decaying carcass. To effect this operation, they remove the earth from beneath the dead body, which sinks into the hollow, and is afterwards covered with the looser soil of the excavation. Their sense of smell, like that of many other insects, is extremely delicate, and no sooner has any of the smaller quadrupeds perished, than one or more of these grave-diggers make their appearance, and in a few hours the corpse is interred. The larvæ are of a lengthened form, of a greyish-white colour, with a brown head. Their bodies are composed of twelve rings, furnished on their anterior and superior portion with a small scaly plate or shield, of a ferruginous brown colour; the shields of the last segments are provided with small elevated points. The head is hard, scaly, and furnished with strong cutting mandibles. The feet are six in number, very short, and attached to the first three segments of the body. When these larvæ have attained to their final term of increase, they descend, it is said, fully a foot beneath the surface, and, forming an oval chamber, the walls of which are strengthened by a coating of a gluey liquid, they assume the nympha state. The perfect insect makes its appearance in the course of three or four weeks. There are seven species of this genus in Britain. Dejean possesses twenty-five. They are all of considerable size, and are chiefly from Europe and North America. We have received a specimen from Persia.[1] *N. vestigator* is black, the club of the antennæ, external margin of the elytra, and two transverse bands, orange yellow. *N. humator*, the most common species in Scotland, is a shining black, with the club of the antennæ ferruginous. Neither *N. mortuorum* nor *N. vespillo* (the species here figured) are very common in Scotland.

---

[1] *Annales des Sciences Nat.* Octob. 1824.

[2] *Règne Animal*, t. iv. p. 491.

[3] *Ibid.* Juil. 1825.

[4] The generic name is supposed to be derived from *Histrio*, a word of Tuscan or Etruscan root, signifying an actor, and was probably bestowed in consequence of their instinctive propensity to simulate death when handled.

[5] For the further divisions of this tribe, see Paykul's *Monographia Histeroideum*; and Leach's *Zoological Miscellany*, vol. iii.

[6] In *Sphærites*, dentations are sometimes found on the internal side.

In Necrodes[2] of Wilkin (Plate CCXXIII. fig. 23) the antennæ are obviously longer than the head, and terminated by an elongated club of five joints, the second of which is larger than the third. Their body is oblong oval, the thorax almost orbicular, widest in the middle. The tibiæ are narrow, elongated, slightly enlarged at the end, and terminated by two ordinary spurs. The elytra are obliquely truncated. We have probably not more than one species in Britain, *N. littoralis* (the species figured), which is black, depressed, and oblong, with the thin terminal joints of the antennæ orange. It occurs on the seashore and the banks of rivers, beneath sea-weed, carrion, &c. and is found on the continent of Europe, along with *N. simplicipes*. The others occur in North and South America, New Holland, and Java.

In the genus Silpha[3] the body is almost shield-shaped and depressed, or but slightly elevated. The thorax is semicircular, truncated, or very obtuse before; the exterior margin of the elytra strongly recurved and guttered; the palpi filiform, with the last article almost cylindrical, and in many terminated by a point. Most of these insects feed on carrion, and thus contribute to the more speedy disappearance of putrid effluvia. Some climb upon plants, particularly the stems of wheat and other grain, where they find small *Helices*, on which they prey. Others dwell on trees, and feed on caterpillars.

The genus was originally of great extent, but has been much modified and circumscribed by Fabricius, Dejean, Latreille, Leach, and others. The species which it now contains resemble their congeners in being of an essentially carnivorous nature—preferring animal substances in a state of putrescence to fresher food. They exhale a disagreeable odour, and, when seized, a thick and dark coloured liquid exudes from their bodies. The larvæ resemble the perfect insects in their habits. They consist of twelve segments, of which the sides are terminated by sharp angles, the terminal segment being furnished with two conical appendages; the head is small, and bears a pair of tri-articulate filiform antennæ, and two strong maxillæ. Like the preceding genus, they undergo their metamorphoses under ground. The species are pretty extensively distributed over the earth, and are rather numerous. Dejean enumerates thirty-four species in his Catalogue, which, however, includes under the generic name of Silpha the genera *Oiceoptoma* and *Phosphuga* of Dr Leach. Of the restricted genus we have not more than eight British species. Most of these are deep black or dark brown. One of the most ornamental is *S. quadripunctata* (Plate CCXXIII. fig. 24), of which the margins of the thorax and the elytra are pale-yellow, the latter with two round black spots on each. We took this rare Scottish insect some years ago near Currie, in the vicinity of Edinburgh. It has since been brought to us from Loch Tay by Dr Greville. It is more frequent in England, where it frequents oak woods for the purpose of preying on lepidopterous larvæ.

Tribe 4th, Scaphidites.

In these the mandibles are cleft or bidentated at the extremity. The tarsi are composed of five very distinct and entire joints. The body is oval, narrowed at either end, arcuated or convex above, and thick in the middle. The head is low, and received posteriorly into a trapezoidal thorax, slightly bordered, broadest behind. The antennæ are generally as long at least as the head and thorax, and are terminated by an elongated mass of five articles. The terminal joint of the palpi is conical. The legs are slender and elongated. With the exception of the *Cholevæ*, the tarsi are nearly the same in both sexes.

In this tribe we place the genera Scaphidium[4] of Olivier, and Choleva of Spence;[5] of the former, *S. maculatum* is the only British species,—the rest inhabiting North and South America, and some of the continental countries of Europe. Of the latter, Mr Spence has described eighteen British species, arranged in three sections, of which some of the constituent parts are referable to the genus *Ptomophagus*[6] of Illiger and Knock, to *Luperus*[7] of Frœlich, and *Catops* of Fabricius and Paykul. Only two or three of Mr Spence's species belong to the genus *Choleva* in its present restricted form.

Tribe 5th, Nitidulariæ.

The Nitidulariæ approach the Silphales in their scutiform and bordered body, but the mandibles are bifid or notched at their extremity; the tarsi seem to consist of only four joints, the first and last, in some, being only visible beneath, where they form but a slight projection,—in others the penultimate is extremely small, in the form of a knot, inclosed within the lobes of the preceding. The club of the antennæ is always perfoliate, of three or two joints, and is usually short or but slightly elongated. The palpi are short and filiform, or somewhat thickest at the extremity. The elytra in several are short or truncated. The legs are but slightly elongated, and their tibiæ frequently widened at the end; the tarsi are furnished with hairs or pellets. These insects are of various habits, according to the species. They occur on flowers, in mushrooms, beneath the bark of trees, and even on putrid meat. This tribe is composed of the genus Nitidula, as subdivided into Colobicus, Thymalus, Ips, Nitidula (proper) (Plate CCXXIII. fig. 25), Cercus, and Byturus.

In the restricted genus Nitidula,[8] the antennæ are short, abruptly clavate, the radical joint large, thick, and somewhat orbicular, the third above one half longer than the fourth, the three last forming a club. Nearly thirty species occur in Britain. Many others are found in Europe and America.

Tribe 6th, Engidites.

These resemble the preceding in the emargination of the extremity of the mandibles, which however project but slightly, and that laterally, beyond the labrum. Their body is oval or elliptical, with the anterior extremity of the head a little advanced in an obtuse or truncated point.

---

[1] For notices of their anatomical structure, see Dufour, in *Ann. des Sciences Nat.* for October 1824 and July 1825.

[2] Probably from *νεκρωδης, cadaverous.*

[3] The word *Silpha*, derived from a Hebrew root, occurs in Aristotle, and appears to have been sometimes used by that author to signify a *cockroach.*

[4] From *Σκαφη, a boat*, and *ιδεα, form.*

[5] *Linn. Trans.* vol. xi.

[6] From *πτωμα, a carcass*, and *φαγω, I eat.*

[7] From *λυπερος, troublesome.*

[8] From *nitidus*, shining, or bright.

The tarsi consist of five distinct joints, entire, and at most only slightly pilose beneath, the penultimate being somewhat shorter than the preceding joint. The antennæ terminate in a perfoliate club of three articulations. The elytra completely cover the abdomen, and the palpi are somewhat thickened at the extremity. Some very minute species live in the interior of houses, and are frequently found on window-sashes. They constitute the genus DACNE, divisible into, 1*st*, *Dacne* proper (*Engis*, Fab. *Erotylus*, Oliv.), in which the antennæ terminate abruptly in a rather large, orbicular, or ovoid and compressed club, composed of crowded articulations, of which the central one at least is much wider than long, and the third longer than that which precedes and follows; the centre of the posterior margin of the thorax is dilated behind or lobed, and the upper extremity of the mentum is advanced, and terminated in a truncated or bidentated point: 2*d*, *Cryptophagus*,[1] Herbst, Lat. (*Dermestes*, Linn. *Ips*, Oliv. *Antherophagus*, Knock), in which the antennæ are moniliform, with the second article as large or larger than the preceding, and terminate in a less abrupt and narrow club than in *Dacne*, and with intervals between its segments. This is a pretty extensive genus, occurring in various parts of the world, but chiefly in European countries. We have fourteen species in Britain.

In Latreille's arrangement (*Règne Animal*, t. iv. p. 508) we now come to certain tribes in which the præsternum is frequently dilated anteriorly in the manner of a chin-cloth (*mentonnière*), and which differ from the preceding in their legs being more or less contractile. The tarsi may be free, but the tibiæ, at least, are folded upon the thighs. The mandibles are short, usually thick, and dentated. The body is ovoid, thick, and furnished with deciduous scales or hairs of various colours. The antennæ are generally straight, and shorter than the head and thorax. The head is sunk into the thorax as far as the eyes. The thorax itself is but slightly if at all bordered; it is trapezoidal, and wider posteriorly, the middle of the posterior margin being frequently somewhat prolonged or lobate. The larvæ are pilose, and dwell for the greater part on the skins or carcasses of animals. They are hurtful in museums. Those in which the legs are not completely retractile, the tarsi being always free, and the tibiæ lengthened and narrow, form

TRIBE 7TH, DERMESTINI.

In DERMESTES proper (so called from *δεϱμα*, *skin*, and *εσθεω*, *to eat* or *consume*) the antennæ are shorter than the thorax, the radical joint large and ovate, the seven following short and slender, the remaining three forming an ovate compressed club, of which the two lower joints are somewhat dilated in the inner side, the terminal being smaller and rounded. They are not received in a particular groove beneath the thorax. *D. lardarius* (Plate CCXXIII. fig. 27) is black, pubescent, the elytra with a broad cinereous band across the base, in which are three brownish or black spots. In ATTAGENUS the club of the antennæ is proportionlly very large, almost serrated, and composed of three articles, of which the first and last, especially in the males, are the largest. The body is ovoid, short, slightly convex. The terminal article of the maxillary palpi is large and ovoid. In ANTHRENUS[2] the club of the antennæ is more solid than perfoliate, and is in the form of a reversed cone, and lodged in a short cavity, hollowed beneath the anterior angles of the thorax. In the larva state these insects live on dried animal matters, particularly on the contents of entomological cabinets. In that condition they are oval, and furnished with hairs, some of which are dentated; they form aigrettes or tufts, of which the hinder are prolonged in the form of a tail. In the perfect state they are found among flowers. Other genera, such as *Limnichus* of Ziegler, *Trogoderma* and *Globicornis*, Lat., pertain to this tribe.

TRIBE 8TH, BYRRHII.

This tribe is composed principally of the genus *Byrrhus* of Linn., and differs from the preceding in its feet being entirely contractile, the tibiæ being susceptible of being bent upon the thighs, and the tarsi upon the tibiæ, so that the species, when their limbs are thus contracted, appear inanimate and without legs. The latter are usually broad and compressed. The body is short and convex.

In NOSODENDRON, Lat. (of which we have one British example, *N. fasciculare*), the mentum is entirely exposed, large, and buckler-shaped. In BYRRHUS proper the mentum is of ordinary dimensions, and as it were interlocked, at least partially, by the præsternum, of which the anterior portion is dilated. The larvæ of these insects have been studied by M. Wadouer. Their heads are large, their bodies narrow and elongated, with the two terminal segments more extended than the others; the first, or that of the prothorax, presents superiorly a large corneous plate. The genus was confounded by Degeer with *Dermestes*, and with *Cistela* by Geoffroy. The species occur in fields, woods, and sandy places. They are not unfrequent by the side of highways, and although they can fly with facility when they choose, they rarely exercise that faculty. When handled or even approached, they apply their legs and antennæ so close to the body as to exhibit the appearance of a little ball, and in that state they simulate death with great perseverance. Of eight or nine species found in Britain, we shall here name only *B. æneus*, an interesting species, lately added to the British Fauna by the Rev. James Duncan. It is oblong-ovate, brassy green above, scutellum whitish, the elytra irregularly punctured, and without striæ. It was found in an open part of a wood near Newbattle House in Mid-Lothian. It has since occurred under stones on Musselburgh Links, has been taken in Dumfriesshire, and was met with by Dr Greville in considerable numbers near the ferry of Kylestroem in Sutherland. There are thirty-three species in Dejean's collection.

SECTION 2*d*. The CLAVICORNES of this section, although forming a good natural group, can only be characterized by the assemblage of several features. Some which are nearest to the PALPICORNES have antennæ of only nine or even six joints. Others have ten or eleven joints to these organs, which are sometimes scarcely longer than the head, and from the third joint form an almost cylindrical or fusiform club, arcuated and somewhat serrated; sometimes nearly filiform, and as long as the head and thorax. In this case, as well as among most of the other genera of the same division, the tarsi are terminated by a large joint, with two strong hooks at the end. In certain genera, such as *Heterocerus* and *Georyssus*, these parts consist of only four articulations. The form of the body in this section is generally ovoid, with the head sunk up to the eyes in a trapezoidal thorax laterally bordered, and terminated posteriorly by acute angles. The præsternum is dilated posteriorly (the Potamophili excepted), and the legs are imperfectly contractile. They usually occur in water, beneath stones by river sides, or in mud. They form two tribes.

---

[1] From *κϱυπτος*, *hidden*, and *φαγος*, *eating*.

[2] Ανθϱηνη is the ancient name of an insect which dwelt among flowers,—a kind of bee.

TRIBE 1ST, ACANTHOPODA.[1]

Remarkable for their broadish flattened legs, armed exteriorly with spines. The tarsi are short, of four articulations,[2] the hooks of ordinary size. The body is depressed, and the præsternum dilated. The antennæ are rather longer than the head, arcuated, and composed of eleven joints, of which the last six constitute an almost cylindrical and slightly serrated club, the second being short and not dilated. This tribe is composed of the single genus HETEROCERUS[3] of Bosc (Plate CCXXIII. fig. 26).

TRIBE 2D, MACRODACTYLA.[4]

Here are included such of the Clavicornes as have simple narrow tibiæ and lengthened tarsi, all composed, except in Georyssus, of five articulations, the last of which is large, with strong terminal hooks. The body is thick or convex,—the thorax less rounded, and usually terminated on both sides by acute angles.

The type of this tribe is formed by the genus *Dryops* of Olivier—*Parnus*, Fab. We here place the genus ELMIS,[5] of which the species, pretty frequent in Britain, occur in water, beneath stones, or on the leaves of water-lilies. In PARNUS proper (*Dryops*, Lat. Oliv.) the antennæ, shorter than the head, are lodged in a small cavity beneath the eyes, the second joint being compressed and much produced,—concave for the reception of the remaining joints, which form a serrated mass attached by a small peduncle near the base. *P. prolificornis* is oblong, olive brown, villose, with the elytra thickly punctured, and obscurely striated towards the sides and apex. It occurs in moist places by the sides of ponds and marshes, not unfrequent during spring. Here are also placed the genera *Potamophilus* of Germar, *Macronychus* of Müller, and *Georyssus* of Latreille.

FAMILY V.—PALPICORNES.

In this family, as in the preceding, the antennæ are terminated by a kind of club, usually perfoliate, but composed at most of only nine articulations, and inserted beneath the advanced and lateral margins of the head, and scarcely longer than it and the maxillary palpi,—frequently even shorter than these last-named organs. The mentum is large and buckler-shaped. The body in this family is generally ovoid or hemispherical, and arched or convex. The feet in most of the genera are formed for swimming, and these present either four articulations to the tarsi, or five, of which the first is much shorter than the second: the whole are entire.

TRIBE 1ST, HYDROPHILII.

Feet fit for swimming. First article of the tarsi much shorter than the others. Maxillæ entirely corneous. Of this tribe (genus *Hydrophilus* of Geoffroy) Linnæus formed only a division of his genus Dytiscus. Their anatomical structure however differs in many important particulars from that of the true Dytisci. The digestive canal, which is four or five times as long as the body, presents a strong analogy, both in its length and texture, to that of the Lamellicornes, and differs from that of the Carnivora except as regards the biliary vessels. We perceive neither the swimming bladder nor the excrementitial apparatus, such as these exist among the Hydrocanthari. In the females only, the latter is replaced by secreting organs fitted for the formation of a cocoon to contain the eggs. The sexual organs of the male bear a great resemblance to those of the preceding family. These and other considerations have induced M. Latreille to place them here. The species are more convex in their general forms than the Dytiscidæ, and their antennæ are dissimilar; but in many of their instincts and habits of life, and in their general transformations, they bear a resemblance to that group. The largest water insect of Great Britain (*Hydrophilus piceus*), which we have failed as yet to discover in Scotland, belongs to this division. Many species are also extremely minute.

In the genus HELOPHORUS of Leach (from ἕλος, *a marsh*, and φορεω, *I penetrate*) the antennæ are shorter than the head, the first joint is the longest, robust, and slightly curved, the second shorter than the first, the three following minute, the last four forming the club. *H. aquaticus* (Plate CCXXIII. fig. 29) abounds in almost every pond. It is almost always found covered with mud, in such an ingenious manner that, when feeding in its little pool, it is with difficulty distinguished from the subjacent soil, either by its natural enemies, or the no less dangerous eye of the practical entomologist. *H. granularis* is more frequently found upon the wing in situations remote from water. In HYDROCHUS of Germar (from ὕδωρ, *water*, and οικεω, *to inhabit*) the general form is narrower and more elongated, the thorax like a lengthened square, and the eyes prominent. *H. brevis*, a rather scarce species, occurs in the Edinburgh district in ditches near Craigcrook, and in the Braid marshes. As allied to the preceding genera we may here name ENICOCERUS of Stephens (so called from ενικος, *singular*, and κερας, *horn*). The antennæ are as long as the head, the basal joint long, curved, slightly geniculate at the base, the second ovate-truncate, three or four following very minute and obscure, the last five of nearly equal thickness, penultimate cup-shaped, terminal orbicular. *E. viridiæneus*, of a brassy green, thorax with an oblique groove near each of the hinder angles, and two foveæ in front, the legs piceous. Although a newly described insect, it does not seem at all scarce in Scotland, where it occurs beneath small stones by the margins of water, or imbedded among mud and confervæ. In the genus SPERCHÆUS, Fab. the antennæ have only six joints, and the clypeus is emarginate. In HYDROPHILUS,[6] properly so called, of Leach, the tarsi are identical in both sexes and not dilated, the pectoral spine terminates with the præsternum, and the scutellum is proportionally small. *H. caraboides* is the only British species. The genus HYDROUS of the last-named author[7] (*Hydrophilus*, Lat.) is characterized by the great extension backwards of the sharp-pointed sternal spine, and by the triangular-shaped dilatation of the last article of the two anterior tarsi of the males. The scutellum is large. *H. piceus* (Plate CCXXIII. fig. 28), the only British species, is one of the largest of the European Coleoptera. It measures above an inch and a half in length, is of an oval form, a blackish-brown colour, with a polished or shining surface. The club of the antennæ is partly reddish. A few slight striæ are visible on the elytra, of which the posterior extremity is rounded posteriorly, and prolonged to a small tooth at the inner angle. This fine insect flies well and swims swiftly, but is inefficient as a pedestrian. When held loosely in the hand it sometimes inflicts a wound with the point of the sternum. The female constructs an ovoid cocoon, arcuated, and of a brown colour. Its exterior tissue is composed of a gummy paste, at first somewhat fluid, which soon hardening, becomes impenetrable by water. The eggs which it envelopes are symmetrically disposed, and kept in their position by a sort of whitish down. These cocoons float in the water.[1] The larva is depressed, blackish, and rugose; the head reddish brown, smooth, round, and capable of being drawn backwards. This peculiar faculty gives it the power of seizing whatever small shells or other living prey it may perceive floating on the surface. Its back serves it as a kind of table, on which it bruises its prey. The bodies of these predaceous larvæ become very flaccid as soon as they are caught. They swim with facility, and are provided beneath the anus with two fleshy appendages, which serve to maintain them at the surface of the water when they ascend to breathe.[2] They are called on the continent *vers-assassins*, on account of their greedy and ferocious nature. They become more herbivorous in the perfect state.

---

[1] From ακανθα, *a thorn* or *spine*, and ποῦς, *foot*.

[2] According to the accurate Gyllenhal, there are actually five, the first being small and oblique. (*Insecta Suecica*, t. i. p. 138.)

[3] From ἕτερος, *different*, and κερας, *horn*.

[4] From μακρος, *long*, and δακτυλος, *finger*.

[5] The name is applied by Galen to a species of intestinal worm.

[6] From ὕδωρ, *water*, and φιλος, *a lover*.

[7] *Zoological Miscellany*, vol. iii. p. 94.

In LIMNEBIUS of Leach (from λιμνη, *a marsh*, and βιος, *life*), the antennæ are short, slender, the club six-jointed; the maxillary palpi longer than the antennæ, with the terminal article shorter than the preceding, and cylindrical. In this tribe are likewise included the genera *Hydrobius* and *Berosus*.

TRIBE 2D, SPHÆRODIOTA.

These Palpicornes differ from the preceding in being terrestrial. Their tarsi consist of five distinct articulations, of which the first is at least as long as the following. The maxillary palpi are shorter than the antennæ, with the third joint larger, inflated, and in the form of a reversed cone. The maxillary lobes are membranous. The body in this tribe is almost hemispherical, with the præsternum prolonged to a posterior point, and the tibiæ spinous, the anterior being palmated or digitated in the larger species. The antennæ are always composed of nine articles, or simply of eight, if we regard the terminal one as an appendage of the preceding. The genera are CERCYON of Leach, and SPHÆRIDIUM[3] of Fabricius (Plate CCXXIII. fig. 30). The former is abundant in Britain, where we find about sixty species, many of which occur in Scotland.[4] Few are as yet ascertained to inhabit extra-European countries, although one or two occur in North and South America. All the species of this tribe are of small size. They usually occur in cow-dung, and excrementitious matter. Some are found on the margins of water.

FAMILY VI.—LAMELLICORNES.[5]

This is the last family of the pentamerous Coleoptera, and one of the most remarkable of the order,—whether we consider the great size of many species, the singularly varied forms of their head and thorax, or the richness of the metallic colouring with which the vegetable-eating kinds are frequently adorned.

The antennæ, inserted in a deep groove beneath the lateral margin of the head, are always short, and composed generally of nine or ten articulations; they are always terminated in a club or mass, which usually consists of three joints, expanded in the form of thinnish plates or leaves, disposed in various ways,—like the spokes of a fan, the leaves of a book, the teeth of a comb, or a series of funnels placed above and within each other. The body is generally ovoid or oval, and thick. The exterior edge of the two anterior tibiæ are toothed, and the articles of the tarsi, with the exception of certain males, are entire, and without brush or pellet beneath. The anterior extremity of the head is advanced and dilated in the form of a clypeus or epistoma. The mentum is usually large, covering the ligula, or incorporated with it, and bearing the palpi. The mandibles of many are membranous, a character scarcely if at all to be observed in any other Coleoptera. The males are frequently very different from the females, being distinguished by horn-like elevations on the head and thorax, and by the greater size of the mandibles. Linnæus indeed founded the sections of his great genus Scarabæus in accordance with these peculiar projections, while Scopoli assumed the spines or teeth of the fore-legs as the distinguishing characteristic of his subdivisions. The latter author likewise proposed two other methods, one of which regards the number of articulations in the clava of the antennæ, and the other takes into consideration the varying manners of the insects themselves. The former of these is extremely defective, the second is chiefly deserving of consideration as exhibiting the first attempt ever made towards a natural arrangement of these insects. They are divided into *Anthophylli*, *Phyllophagi*, and *Stercorei*.

Degeer was the first to avail himself of the improvements indicated by Scopoli, while at the same time he avoided his principal imperfections. He arranged the Scarabæi into three families, as follows: 1*st*, *Scarabées de terre*; 2*d*, *Scarabées des arbres*; 3*d*, *Scarabées des fleurs*. Oryctes and Trox were no longer regarded as phyllophagous insects.

Geoffroy separated from Scarabæus of Linnæus the exscutellated species under the name of *Copris*, and Scopoli's genus Lucanus under the name of *Platycerus*. The institution of the genus Copris was certainly an improvement, although it was founded on such defective characters, that coprophagous insects, such as the family Geotrupini of Latreille, were included in the same genus with Cetonia, from which they might have been perceived to be distinct so soon as the necessity was admitted of carrying the investigation among the *Lamellicornes* somewhat beyond that first affinity—the form of the antennæ.

At a still later period Fabricius further improved upon the heterogeneous composition of Geoffroy's genus Scarabæus, by taking from it the genera *Trox*, *Melolontha*, *Cetonia*, and *Trichius*. But the re-union of Geoffroy's genus Copris with Scarabæus was a retrograde step which the entomologist of Keil afterwards corrected in a supplementary work. The connection, however, between the insects afterwards named *Geotrupes* by Latreille and the genus Copris of Geoffroy, was so far re-established by the formation of the Fabrician genus Scarabæus.

Olivier adopted the genus Scarabæus of Fabricius, with all his other genera except Trichius, and divided it into

---

[1] For a detailed and accurate account of the structure and transformations of this insect, see a posthumous work of the celebrated Lyonnet, lately published under the title of *Recherches sur l'Anatomie et les Metamorphoses de differentes espèces d'Insectes.*

Coleoptera Pentamera.

the following sections: 1*st*, Those furnished with mandibles, but unprovided with a labium; 2*d*, those furnished with mandibles and a labium; 3*d*, those which have neither mandibles nor labium. The three groups just mentioned are characterized by Mr Macleay as strictly natural.[1]

This important family, in the system of Latreille, seems to include all those insects classed by Linnæus in the old genera *Scarabæus* and *Lucanus*. The lamellicorn tribes, indeed, include a very numerous assemblage, many of which, especially such as feed on flowers and living vegetation (called *Thalerophaga* by Macleay), are remarkable alike for beauty of form and splendour of colour. Most of those, however, which feed on decomposed vegetables, or excrementitious substances, are usually of a more uniform black or brownish hue. But even the coprophagous kinds sometimes surprise us by their beauty, and present a singular contrast when disentangled from their repulsive habitations. They are all winged insects, although for the most part rather dull and heavy in their movements.

The larvæ are long, semi-cylindrical, soft, of a whitish colour, and divided into twelve rings or segments. The head, of a harder consistence, is armed with strong mandibles. The feet are six in number, and squamous or of a scaly texture. On each side of the body there are nine stigmatic openings. The posterior extremity is the most bulky; it is rounded and almost always curved inwards, in such a manner as to prevent the larva from extending itself in a straight line. Its motions are consequently slow and awkward, and when crawling on the surface it frequently rolls over or falls on one side. The nympha or intermediate state is in some instances not assumed till after the lapse of several years. Immediately preceding the assumption of that state the larva protects itself by means of a cocoon of an oval form, composed of earth and the gnawed fragments of other materials, agglutinated by a viscous secretion which exudes from its body. These larvæ seek their food in the dung of cattle, in tan pits, in gardens where rich vegetable mould occurs, and among the roots of plants. In regard to their interior structure, it has been observed that the nervous system, when studied in the different stages of life, presents a considerable dissimilarity. The ganglions are less numerous, and approximate more to each other, when the insect has reached the term of its final transformation; and the two posterior ganglia throw out numerous filaments disposed in a somewhat radiated form. In the larva the trachea is elastic, but simply tubular in the perfect insect. The structure of the eye in most of the lamellicorn beetles exhibits characters analogous to those of the Tenebrionites, the Blattæ, and other lucifugous or light-shunning species.

The alimentary canal is of great length, especially among the coprophagous kinds; and the chylific ventricle is beset with papillæ, which, according to the investigations of M. Dufour, serve as the receptacles of the alimentary fluids. The biliary vessels resemble those of the carnivorous Coleoptera in number and position, but they differ in being of greater length and much more slender. Latreille divides this important family into two tribes.

TRIBE 1ST, SCARABÆIDES.[2]

These correspond to the unrestricted genus *Scarabæus* of Linn. Their antennæ are terminated by a foliaceous club, generally capable of being alternately closed or expanded; or are composed of joints that fit into each other, either in the form of a reversed cone, or nearly globular. The mandibles are of identical form, or nearly so, in both sexes; but the head and thorax of the males frequently exhibit projections or peculiar forms. The antennæ in the latter sex are frequently more fully developed than in the females. The alimentary tube in these insects is generally much longer than that of the following tribe, and the œsophagus is proportionally shorter. But it is chiefly by the genital system of the males that the Scarabæides are distinguished, not only from the tribe with which they are conjoined, but from all other pentamerous Coleoptera. The larvæ have a cylindrical stomach surrounded by three ranges of small cæca, the small intestine very short, the colon extremely thick and turgid, and the rectum of moderate size. A prodigious accession of fine typical forms has been received of late years by this division of Entomology, far beyond what we are able to indicate in this work.[3] We shall, however, notice the most important and remarkable genera, and illustrate many of these by means of the plates connected with this department of the Encyclopædia.

The following sections are established on the consideration of the masticating organs, the antennæ, and the habits, and have been confirmed by the anatomical researches of M. Dufour.

SECTION 1ST, COPROPHAGI.[4]

In some of these the antennæ are formed of nine, in others of only eight articulations; the three terminal ones forming the club. The labrum and mandibles are membranous and concealed. The terminal lobe of the maxillæ is also of the same consistence, broad and arcuated at the upper margin, and curved inwards. The terminal article of the maxillary palpi is always the largest of all, nearly oval or almost cylindrical; but that of the labial palpi is almost always more slender than the preceding, or very small. Behind each of these latter palpi is a membranous projection, in the form of a ligula. The mentum is emarginate. The sternum presents no particular projections, and the hooks of the tarsi are always simple. The anterior tarsi are frequently wanting in certain species, either naturally or because they are deciduous. The extent of the alimentary canal is always very great, occasionally (as in *Copris lunaris*) even ten or twelve times the length of the body. The chylific ventricle occupies the greater portion; it is beset with papillæ, conoid or in the form of nails, folded on itself, and maintained in that state of agglomeration by numerous tracheal bridles. The intestine is filiform, but terminates in an enlargement. "Les testicules des coprophages disséqués par M. Dufour, lui ont paru composés de six capsules spermatiques, orbiculaires, un peu deprimées ordinairement réunies, par des trachées, en un paquet, portées chacune sur un pédicule tubuleux, assez long, et qui aboutit à un canal déférent de peu de longueur. Il n'y a qu'une paire de vesicules séminales; elles sont filiformes, très longues et fort repliées."[1] Our present section corresponds to the third division of the genus Scarabæus of Olivier (*Copris*), with the addition of some other Scarabæi (*Aphodii*) of that author.

---

[1] *Hor. Ent.* p. 17.

[2] The *Scarabæidæ*, as restricted by Macleay, are chiefly tropical forms, that is, the species in the warmer regions of the earth are to those from beyond the tropics nearly as five to one. Out of 450 species and upwards, in the collection of Mr Macleay senior, only nine are natives of England, and of these eight are *Onthophagi*.

[3] Comte Dejean informs us that his collection now contains 2060 species of *Lamellicornes*, among which he has found himself under the necessity of establishing 76 new genera.

[4] From Κοπρος, *dung*, and φαγος, *eating*.

*

> In some the intermediate pair of legs are much more remote from each other at the base than the rest; the labial palpi are hairy, with the terminal articulation much smaller than the others, or even indistinct; the scutellum is either null or extremely small.

Coprophagi of this division, peculiar to the eastern continent, with a rounded body, usually depressed above, or but slightly convex, similar or differing little in the sexes, and without horns; the antennæ of nine joints, terminated by a foliated club; without either scutellum or a sutural hiatus indicating its place; the four posterior tibiæ, usually furnished, as well as the tarsi, with ciliated or hairy fringes, and slender, elongated, not dilated at the extremity, or but slightly so, truncated obliquely, and terminated by a single strong-pointed spur; with the epistoma more or less dentated;—these form the genus ATEUCHUS[2] of Weber and Fabricius. (Plate CCXXIV. figs. 1 and 2.)

The above genus, however, has been since restricted to such species as have the exterior margin of the elytra straight or unemarginated, and without a sinus, near the base, leaving exposed the corresponding portion of the upper margin of the abdomen. The tibiæ and tarsi of the last four legs are furnished with long hairs; the first four articles of the tarsi are generally longer than the others. The first joint of the labial palpi is almost cylindrical, or in the form of a reversed cone. The epistoma is generally divided into three lobes or festoons, and its contour presents six teeth. The *Ateuchi* form the genus *Scarabæus* of Macleay.[3] These insects deposit their ova in dung, which they form into balls, and roll along with their hind legs till they find a hole adapted to receive them, or a softish soil in which they may be buried. Two species were worshipped by the ancient Egyptians, and form a noted and conspicuous feature in the hieroglyphical system of that mysterious nation. We still find them sculptured on their monuments, in various positions, and sometimes of gigantic size. They were also formed into separate figures, as seals and amulets, composed of gold and other precious materials, and hung around the necks of the living, or buried along with their famous mummies. The insect itself in the natural state is also sometimes found in their gaudy coffins.

The *Ateuchus sacer* (Plate CCXXIV. fig. 2) occurs not only in Egypt, where it formed an object of superstitious worship, but over a great portion of the south of Europe. It is also found in the western regions of Asia. Another species, discovered in Sennaar by M. Caillaud, was, however, according to M. Latreille, the first to attract the notice of the Egyptians.[4] It is named *A. Egyptiorum* (ibid. fig. 1), and, instead of being black like the former, is green with a golden hue. The occiput also, instead of being bi-tuberculated, exhibits only a slight elongated eminence, which is smooth and shining.

In GYMNOPLEURUS of Illiger, the exterior sides of the elytra are strongly emarginate near the base. The four posterior tibiæ are in general simply ciliated, or furnished with small spines, and the last article of the tarsi is as long, if not longer, than all the preceding ones taken together. The first article of the labial palpi is dilated internally and almost triangular. There is a fossula on each side of the thorax.[5]

Other Coprophagi, nearly allied to the preceding, and likewise placed by Fabricius among the Ateuchi, are distinguished by the intermediate tibiæ, the extremities of which, as well as of the two hinder ones, are frequently clubbed or dilated, and present two spurs or spines. The epistoma in many has only four or two teeth. The first article of the labial palpi is always larger than the following, and dilated on the internal side. The third and last article is distinct. We shall here name only the genus SISYPHUS, which differs from the others in having only eight joints in the antennæ. The form of the abdomen is triangular, and the intermediate and hind legs are long and narrow, with the thighs clubbed.

In all the ensuing Coprophagi the intermediate and hind tibiæ are always dilated at their extremity, and almost in the form of a lengthened triangle; the intermediate pair terminate, like those of the preceding, in two strong spines; but the head or thorax, or both these parts, of the males, are distinguished by horns or marked projections. In several the last three articulations of the antennæ are semi-cupular, and concentrically fitted into each other. These insects are referable to the genera *Onitis* and *Copris* of Fabricius.

The genus ONTHOPHAGUS,[6] Lat. (ibid. fig. 3) (which, in common with ONITICELLUS of Dejean, has the third joint of the labial palpi small or indistinct, and the preceding larger than the first), exhibits a short body with a thickish thorax, broader than long, and semi-orbicular or nearly orbicular, but strongly emarginate or truncated in front. The head, and frequently the thorax also, is horned in the males. The scutellum is not apparent. Of this genus we have eight or ten species in Britain. Dejean's Catalogue contains 150. Some beautiful species of small size occur in Africa and the East Indies. They are likewise met with in New Holland, where they constitute the principal portion of the coprophagous beetles, which seem rare in that vast region, a circumstance attributed by Mr Macleay to the absence of all large herbivorous mammalia, except of the marsupial kind.

Two other genera, furnished with a scutellum or a sutural hiatus, with the anterior legs often deprived of or unprovided with tarsi, and frequently long, slender, and curved in the males, are distinguished from all other Coprophagi by the form of the club of the antennæ; its first joint (or the seventh of the whole, counting from the base) being sub-triagonal, and receiving within it the ensuing, of which the inner margin is shaped like a horse-shoe; the third or terminal article is in the form of a reversed cupula. The thorax is large, and usually exhibits two depressions near the middle of its posterior margin. In Onitis, Fab., the second article of the labial palpi is the largest of all; and the scutellum, though small and sunken, is yet visible. The anterior legs are generally long, slender, and curved in the males, and the tarsi are often absent. The thorax, with a few exceptions, is without horns. In Phanæus of Macleay (Copris, Onitis, Fab.), Plate CCXXIV. fig. 4, the first article of the labial palpi is the largest, and dilated on the inner side. A simple sutural void indicates the place of the scutellum. This genus is composed of large and beautiful species, chiefly from the equinoctial regions of the new world. The males differ greatly from the females in regard to the horn-like processes which frequently characterize the head and thorax of the former; but the respective length of the legs does not differ between the sexes, as in the preceding genus.

---

[1] *Règne Animal*, t. iv. p. 531.

[2] Probably from α priv. and τευχος, *an instrument of war*, the head being unarmed.

[3] The genus Scarabæus of Macleay (Ateuchus of most modern authors) is proper to the ancient world. Of the forty-three species which compose its five types, as exposed in the *Horæ Eutomologicæ*, twenty-seven occur in Africa. The first type extends from the Atlantic Ocean to Thibet, and from Austria to the Cape of Good Hope. It contains the following species:—*S.* (HELIOCANTHARUS) *sacer*, *Dufresnii*, *pius*, *Bonelli*, *Hottentotus*, *impius*, *Lamarckii*, *Cuvieri*, *Sanctus*, *Palæmon*, *intricatus*, *puncticollis*, *Spencii*, *Degeeri*, *Savignii*, *morbillosus*, *laticollis*, *variolosus*, *semipunctatus*. Type second contains as yet only a single species, from the north of Africa, *S.* (MNEMATIUM) *Ritchii*. The third type seems confined to the south of Africa, and includes *S.* (PACHYSOMA) *Æsculapius* and *Hippocrates*. The existence of the fourth type is inferred upon general principles, and from an observed hiatus in the series of affinities, but has not yet been specially detected. The fifth type inhabits all that tract of country which extends from the Atlantic Ocean to the Chinese Sea, and from Paris to the Cape of Good Hope, and contains *S.* (GYMNOPLEURUS) *azureus*, *nitens*, *mundus*, *sinuatus*, *pilularius*, *Sturmii*, *atronitidus*, *flagellatus*, *humanus*, *Leei*, *Bufo*, *fulgidus*, *cærulescens*, *affinis*, *cyaneus*, *Kœnigii*, *granulatus*, *parvus*, *miliaris*, *spilotus*, *maculosus*.

[4] *Description des Insectes recueillis par M. Caillaud*, forming part of his *Voyage en Nubie*.

[5] For the other genera, see *Règne Animal*, t. iv. p. 405. Consult also *Hor. Ent.* p. 494.

[6] From ὀνθος, *dung*, and φαγος, *eating*.

The genus Copris[1] (Plate CCXXIV. fig. 5), as now restricted by Latreille, contains those species only the antennæ of which are terminated by a trifoliate club; the four anterior tibiæ strongly dilated and truncated at the extremity; both scutellum and hiatus wanting; the body thick, and differing on its upper surface in the sexes; and the labial palpi composed of three distinct joints, of which the first is the largest, almost cylindrical, and not dilated on the inner side. The largest species of this numerous genus (there are eighty-four in Dejean's collection, of which, however, scarcely half a dozen are European, and only one, *C. lunaris,* occurs in England) are indigenous to the warmer countries of Asia and Africa.[2] Many species are likewise native to the new world.

* *

In others the legs are inserted at equal distances from each other; the scutellum is distinct; the labial palpi smooth, or but slightly haired, with the third and terminal article larger, or at least longer, than the preceding.

In the genera of this subdivision of the Coprophagi the elytra entirely envelope the contour of the abdomen, to which they form as it were an arched covering,—a character by which they approach the ensuing section. They are, however, closely related, by the structure of their legs and antennæ, to the preceding genera; although the sexual differences are less pronounced or apparent, and frequently consist merely in small tubercles instead of horns. All the species are of small size, and some of them are among the most frequent of the British Lamellicornes. They constitute the family *Aphodiidæ* of the English entomologists. These insects are extensively distributed over the whole of the north temperate zone; and Mr Macleay has made out the proportion of tropical species to be to those from countries beyond the tropics as one to eight. According to the same authority, none have hitherto been brought from New Holland, although several occur at the Cape of Good Hope, which is nearly of the same south latitude. It is probable, however, that if the marine detritus of New Holland were properly searched, some insects at least approaching to *Psammodii* in habit would occur.[3]

Although these insects closely resemble each other in general structure, they yet differ rather widely in their modes of life. They are not all coprophagous, strictly speaking, for several prefer vegetable matter, for the most part marine, in a state of putrescence. We shall notice the two principal genera. In Aphodius,[4] Fab. (Plate CCXXIV. fig. 6), the last article of the maxillary palpi is cylindrical, and that of the labial more slender than the preceding. The maxillæ have no appendage, or corneous and dentated lobe, on the inner side. The species of this genus are slow of foot, but they fly with facility; and their appearance is interesting, as denoting the "ethereal mildness" of returning spring. They are common in cow pastures. We received the species figured on the plate referred to (*A. bipunctatus*) from the south of Russia. Above fifty species occur in Britain, and three times that number are known to naturalists. In *Psammodius*, Gyllenhal (so named from ψαμμωδης, sandy, in reference to the places of their most frequent occurrence), the last article of the palpi is almost oval, and longer and thicker than the others, and the internal lobe of the maxillæ is corneous, and divided into two dentations.

Section 2d, Arenicoli.

The groups of this section have one character in common with the two genera last mentioned, that the elytra entirely cover the posterior extremity of the abdomen; but their other features are distinctive. The labrum is coriaceous, and generally projects beyond the epistoma. The mandibles are corneous, and usually curved and salient. The terminal lobe of the maxillæ is straight, and not curved inwards. The third and last article of the labial palpi is always very distinct, and always at least as long as the preceding. With few exceptions, the antennæ consist of from ten to eleven articulations. Like the preceding insects, however, these also live in dung, beneath which they dig holes in the earth. Their principal period of flight is during the evening, after sunset. When touched they counterfeit death.

*

In this subdivision the labium is terminated by two lobes or projecting ligulæ; the mandibles are generally salient and curved; the labrum is exposed in whole or in part; the antennæ, in the greater number, are composed of eleven articulations. The body is black or reddish, with the elytra smooth or simply striated. The males are generally distinguished from the females by horn-like projections and other external characters. They affect more especially excrementitial substances.

In the genera Ægialia of Lat. and Chiron (Plate CCXXIV. figs. 7 and 11) of Macleay, the antennæ are only nine jointed. In the latter their terminal club is rather semipectinated than foliated, and the species are placed by some with *Passalus.*

In the subsequent genera the antennæ are considered to consist of eleven joints, although the computation varies according to the view which may be adopted of the exact structure of the articulations. The genus Lethrus, Scopoli, is distinguished from all the others by the form of the antennal club, like a reversed cone, and composed of leaflets contorted into a kind of funnel, and fitted concentrically into each other; and by the mandibles, which are entirely dentated and serrated on their inner side, and present a corneous advancement underneath, especially in the males. *L. cephalotes* is said to be extremely injurious to cultivated grounds, where it attacks the scarcely visible buds and leaves of plants, cutting them cleanly off with its mandibles. It is hence called *Schneider* in Hungary, where it sometimes proves very hurtful to the vines. This species (there are only two or three others known) lives in holes in the earth, and fierce battles take place during the nuptial season between the males when aspiring to the favour of the gentler sex. The antennal club of the remaining Arenicoli is composed of ordinary-shaped leaflets, placed one on another like the leaves of a book. In Geotrupes of Lat. (Plate CCXXIV. figs. 9 and 10) named from γη, *the earth*, and τρυπαω, *to bore*, in reference to their excavating propensities, the club of the antennæ is oval or ovoid, and the edges of all the leaflets are perceptible even when the part is contracted. The labrum forms a transverse square, entire, or simply dentated. The mandibles are curved, greatly compressed, dentated at the extremity, and frequently sinuated on the inner side. The species are pretty numerous, and occur both in Europe and America. Some are common in Britain, especially *G. stercorarius*, a large black beetle, with brilliant metallic blue or purple reflections on the under surface, well known as "wheeling its drowsy flight" during fine evenings. We have often been amused by the different devices made use of by insects to deceive their enemies. While the Byrrhidæ, and several other tribes already alluded to, contract their limbs when alarmed, so as to give themselves the appearance of a little ball of inert matter in no way tempting to any insectivorous creature, the species above named pursues an opposite line of conduct, and sticks out its legs at full length, where it holds them perfectly still and rigid, so as to produce the same appearance as if it had been long deprived of life. It is thus supposed to deceive the cunning rook and other birds, which value it chiefly as a living prey.[1] In Bulboceras[2] of Kirby (Plate CCXXIV. figs. 12, 13, and 14), one of the mandibles is simple at the extremity, while the other is dentated. The genus is also distinguished from the preceding (in common with *Athyreus* and *Elephastomus* of Macleay) by having the club of the antennæ large, orbicular, or nearly globular, with its first and last leaflet, when the part is contracted, completely enveloping the tenth or intermediate, and forming for it a kind of box (see figs. 13 and 14).

---

[1] From κοπρος, *dung.*

[2] The fine insect which, following the nomenclature of M. Fischer of Moscow (*Entomog. de la Russ.*), we have represented as an *Ateuchus* (see Plate CCXXIV. fig. 8), is, we understand, regarded by Latreille as belonging to the genus *Copris.*

[3] *Hor. Ent.* i. p. 58.

[4] From αφοδος, *dung.*

In *Hybosorus* and *Acanthocerus* (placed in different families, the former in *Geotrupidæ*, the latter in *Trogidæ*, by Macleay[3]), the antennæ consist, as in most of the subsequent Scarabæides, of ten articulations.

* *

In this our second subdivision of the Arenicoli, the antennæ, scarcely longer than the head, are composed of ten articulations, of which the first is large and hirsute. The ligula is entirely concealed by the mentum. The labrum and mandibles are but little exposed, and the latter are thick. The palpi are short, the mentum very hairy. The inner side of the maxillæ is armed with teeth. The body, of a cinereous or earthy hue, is rough or tuberculated on the upper surface. The head is inclined, and terminates in an angle or point. The thorax is short, transversal, without lateral borders, sinuated posteriorly, with the anterior angles advanced. The abdomen is large, arched, and covered with very hard elytra. The anterior legs are advanced, and their thighs cover as it were the lower surface of the head.

These insects form the genus Trox[4] of Fabricius and Olivier. They generally occur on sandy soils, and are supposed by Latreille to feed on the roots of plants. We suspect that our knowledge is still extremely vague regarding their habits of life and modes of transformation. It is certain that they are attracted by dried bones and other cadaverous remains, but it is difficult to determine whether this is owing to the peculiar colour, or the nature of the animal substance. Pallas observes, "sub cadaveribus æstivo ardore exsiccatis cum Histeribus et Dermestibus hospitatur;" but it by no means follows from that peculiarity of position that the insect partakes of the carcass, any more than that numerous other species which seek the secure covering of a rock or mass of stone, are in the habit of devouring these inorganic matters. We may further remark that the Troges are the only petalocerous insects among which we find an apterous species,—the *T. horridus* being destitute of wings. It forms the genus *Phoberus* of Macleay, and is worthy of consideration as probably destined, when its habits are better known, to throw some light, either by agreement or opposition, on the history of its congeners, and the value of the groups into which they have been divided. These in general are supposed to delight in cadaverous substances: all insects intended to live on animal matter, partially distributed and collected in masses, are provided with wings, which convey them rapidly (with the joint guidance of the sense of smell), to those decaying objects which they instinctively desire; but the species above named being destitute of wings, a doubt naturally arises as to the probability of its feeding, like its congeners, on dried cadaverous matter. It has been stated as an illustration of this point, that the genera *Silpha*, *Hister*, *Dermestes*, and other necrophagous kinds, are winged, whilst *Pimelia*, *Brachycerus*, &c. which, like *T. horridus*, frequent sandy deserts, are apterous,—a formation supposed to accord with the fact that the particles of which their food is composed are so universally spread over these arid plains as to obviate the necessity of any rapid or extended change of place.[5]

Section 3d, Xylophili,[6] Lat.

In these the scutellum is always distinct, and the elytra do not cover the posterior extremity of the abdomen. In several the hooks of the tarsi are unequal. The antennæ have always ten articulations, of which the last three form a foliated mass,—the central leaflet being never entirely concealed or inclosed by the others. The labrum is not projecting, and only its anterior part is exposed. The mandibles are entirely corneous, and laterally project beyond the head. The maxillæ are corneous, or of a solid texture, straight, and usually toothed. The ligula is covered by an ovoid or triangular mentum, narrowed and truncated at the extremity, where the angles are frequently dilated. All the legs are inserted at equal distances from each other.

*

A first subdivision contains those genera in which the males are distinguished from the females by tubercles or horn-like projections on the head or thorax, and sometimes by a difference in the form of the latter part. The epistoma is small, triangular, and either pointed, truncated, or bidentated at the end. The labrum is almost always concealed. In some the maxillæ terminate by a simple coriaceous or crustaceous lobe, more or less hairy, and without teeth; in others they are entirely squamous or scaly, pointed, and provided with a small number of teeth, accompanied by hairs. The mentum is ovoid, or truncate-triangular. The chest exhibits no projection. The hooks of the tarsi are generally equal. The scutellum is small, or of medium size. The colours incline to black and brown.

[4] Τρωξ, from τρωλῶ, *I gnaw*.

[5] *Hor. Ent.* pp. 120 and 136.

[6] From Ξυλον, *wood*, and φιλος, *a lover*.

Of those genera in which the maxillæ are terminated by a coriaceous or crustaceous lobe without teeth, and simply hirsute or furnished with cilia, we shall adduce as an example ORYCTES[1] of Illiger (Plate CCXXIV. fig. 15). The legs of these differ but little in length, and the four posterior tibiæ are thick, strongly incised or emarginate, with an extremity greatly widened, and appearing as if stellated in some. This genus contains some large and striking species, such as *O. rhinoceros*, and others, from the East Indies. There are few European species, and of these *O. nasicornis* is by some regarded as indigenous in England. It feeds on tan and rich vegetable mould. Its larva is well known as having furnished the great Swammerdam with the subject of one of his many remarkable anatomical investigations.

Of such as possess maxillæ which are usually corneous or scaly, and more or less dentated, we shall mention the genus SCARABÆUS[2] properly so called (Plate CCXXIV. fig. 17). In these the body is thick and convex, and the external side of their mandibles sinuous or dentated. These insects occur chiefly in the equatorial regions, both of the old world and the new. They are scarcely known in Europe, and do not exist in Britain. *S. punctatus* is found in Italy and the south of France, and *S. monodon* in Hungary. Several species from South America (such as *S. Hercules*) and the East Indies, are remarkable for their gigantic size and extraordinary structure. *S. Atlas*, Fab. (*Hector* of Dejean?), is a native of Java, but it also occurs in the mainland.[3] We know little of the actual history or transformations of these fine insects, but their habits may be inferred to resemble those of *Oryctes*, and other congenerous tribes of the Scarabæides. The larvæ probably dwell in the decaying portions of great timber trees, and no doubt hasten the death and overthrow of these sylvan monarchs. We could dilate with pleasure on the singular aspect of these gigantic Coleoptera, did not the nature of our general plan, and our desire to notice, however briefly, most of the principal genera, preclude our entering into the descriptive details of species. We must therefore rest satisfied with a general reference to the works of Olivier, Fabricius, Latreille, Macleay, and the Catalogue of Dejean, part ii. p. 150.[4] We cannot help, however, here alluding to that principle of association in the human mind, by which size or dimension affects us with such different ideas in relation to different objects. Many may smile at our using the expression "gigantic" or "magnificent" to creatures the largest of which (of the Coleopterous kinds, e. g. *Prionus gigas*) scarcely exceeds six inches in length;—yet true it is, that to an entomologist accustomed only to the European forms of insect life, the first sight of any of the greater Prionidæ, or of *Scarabæus Hercules*, or *Atlas*, or *Actæon*, creates a feeling bordering upon awe, such as that which an enlightened artist may be supposed to experience on first beholding the perfect proportions of some great temple. Our ideas are perhaps equally relative in all departments both of art and nature. An Egyptian pyramid is thought *stupendous*, while North Berwick Law (of about equal height with the greatest of the Coptic monuments) is almost nameless as a Scottish mountain. An eagle, from his size and strength, is called a "feathered king," although his body is less than that of a pig a few months old. A mastiff or Newfoundland dog, being among the largest of the canine kind, is called "majestic," although a sucking elephant might squeeze both of them to death by an accidental stumble,—the said elephant being at the same time regarded as a "poor creature," because it is not a full grown example of the "wisest of beasts." An ancient walrus, floating among the hoary icebergs of the arctic seas, is looked upon as one of the most ponderous of created things; yet a Greenland seaman considers as insignificant, and will scarcely throw his harpoon into the sides of a young whale, which with one blow of its upraised tail could lash the ocean into foam, sink a "captain's gig," and send the walrus with a fractured skull to the bottom of the sea. The same principle is capable of illustration, by the practice of the more enthusiastic disciples of Isaac Walton. Even the most experienced of anglers gazes with delight, almost with wonder, at a river trout of three or four pounds weight. A grilse of the same dimensions, when made to "spurn the indignant shore," is viewed by the salmon fisher almost with a feeling of disappointment. We remember our friend Sir William Jardine killing, *inter alia*, one morning in the Tweed, a salmon of six and thirty pounds weight, in an hour and five minutes, and yet the same skilful angler was greatly astonished by a Loch Awe trout, which, though a giant of its kind, was, when brought to the balance, found wanting by several ounces, in the weight of twelve pounds. But to return to our beetles.

The genus PHILEURUS of Lat. (*Geotrupes* of Fabricius) differ from the Scarabæi in their mandibles, which are straighter, without sinus or dentation on the outer side;

---

[1] *'Ορυκτὴς, one who digs.*

[2] The term *Scarabæus* appears to have been either applied by the Romans to coleopterous insects in general, or at least to have been used with a wide and indefinite generic application. The origin of the word is by no means clear, and its derivation from *σκάπτω*, as given by Fabricius and Olivier, has been regarded as inconsistent with the rules of etymology. Mr Macleay thinks it difficult to obtain the word at all from the Greek, and regards it rather as being of Etruscan origin, the more especially as it never occurs in other than ancient *Latin* authors. Let us here note that the *Scarabæi* (properly so called) of Latreille belong to the genus *Dynastes* of Macleay, which includes the "giants of the insect race." We believe, however, that some *Prionidæ* exceed them in size.

[3] The specimen in our collection was *taken at Rangoon* by Sir Archibald Campbell, and obligingly transmitted to us by George Swinton, Esq. We have since received Javanese specimens from Lieutenant Loudon, R. N. of Musselburgh.

[4] Few points are more puzzling, or productive of greater delay in the progress of the student, than the cloud of synonyms by which natural history is overshadowed. This arises partly from ignorance, and partly from the (nearly allied) source of self-conceit, which induce together "confusion worse confounded," in the very face of an expressed desire to enlighten and amend. Even the great masters of the art have sometimes erred in the imposition of their generic names. The reader will bear in mind that *Geotrupes* of Fab. forms no part of the *Geotrupides* of the present day, but corresponds to the genus *Scarabæus* of Latreille; while the genus which bears the latter name in the *Horæ Entomologicæ* is identical in its prevailing parts to the genus *Atcuchus* of the *Systema Eleutheratorum*. There is no doubt that Mr Macleay's genus contains the insects to which the name of Scarabæus was applied by Pliny.

their body is also depressed, and the thorax dilated or rounded laterally. Such are *S. dydimus, vulgus, depressus*, of Fab.

* *

A second subdivision of the Xylophili contains those genera in which the head and thorax are of similar structure in both sexes, and not characterized by peculiar projections. The anterior margin of the labrum is almost always exposed or apparent. The maxillæ are entirely squamous, as if truncated at the termination, and furnished with five or six strong teeth on their inner edge. The mentum is proportionally shorter and broader than that of the Scarabæi, and less narrowed superiorly. The mesosternum is frequently prolonged to a horn or blunt point between or beyond the second pair of legs. The scutellum is usually large. The hooks of the tarsi are generally unequal. A small number excepted, these xylophilous Coleoptera are peculiar to the equatorial regions of the new world. They resemble in many respects our preceding subjects, and are at the same time nearly allied to the Melolonthæ, and particularly the Cetoniæ, of which they bear the external aspect, although their masticating organs differ. Fabricius and Olivier, in fact, arranged most of these insects with each other. The body of the kinds now under consideration is shorter, more rounded, and smoother than that of the preceding. They moreover differ in being frequently ornamented with brilliant colours.

In some (agreeing in this character with all the preceding Scarabæides), we do not perceive, between the posterior angles of the thorax and the exterior ones of the base of the elytra, an axillary piece filling up as it were the space comprised between these parts.

We shall first notice a genus in which the central portion of the chest presents no pointed prolongation. Such is HEXODON[1] (Plate CCXXIV. figs. 16, 20, 22, and 23), of which the body is almost orbicular, plane beneath; the head square, and received into a deep emargination of the thorax; the exterior margin of the elytra dilated and anteriorly marked by a small groove or gutter; the legs slender, and the hooks of the tarsi small and equal. But in the following genera the sternum is prolonged between the second pair of legs to a conical point. In CHRYSOPHORA of Dejean (*Melolontha chrysochlora*,[2] Lat.), Plate CCXXIV. figs. 18 and 19, the hind legs of the male are very large, the thighs thick, the tibiæ arcuated, and terminated at the inner angle by a very strong point. Here is also placed the *Scarabæus macropus* of Shaw.[3] In RUTELA, Lat. (Plate CCXXIV. fig. 25), there is no remarkable difference in the size of the legs in the two sexes; the mentum is almost isometrical; the scutellum small or moderate; and the sternal point is short,—not reaching to the origin of the two anterior feet. The body is ovoid or oval. MACRASPIS, Macleay (Plate CCXXIV. fig. 26), differs from the preceding in the proportions of the mentum, which is obviously longer than broad; in the short and rounded form of the body; in the length of the scutellum, which at least equals a third of that of the elytra; and in the length of the sternal point, the extremity of which attains to the origin of the two anterior legs, or extends beyond it. The mandibles are almost triangular, with the extremity pointed or emarginate. The maxillæ are furnished with several teeth. One of the hooks of the tarsi, at least of the four anterior ones, is bifid, the other entire. Here Latreille places also the genus CHASMODIA of Macleay.

In other genera we perceive the axillary piece, before alluded to (agreeing with that seen in the same quarter in the Cetonia, and named *epimera* by M. Audouin[4]), filling up the space comprised between the posterior angles of the thorax and the exterior angles of the base of the elytra. Such is the genus OMETIS of Latreille.

SECTION 4TH, PHYLLOPHAGI.[5]

This section, as well as the ensuing, is formed from the great genus *Melolontha* of Fabricius, of which certain species are scattered also among the preceding groups. The Phyllophagi are nearly related to the concluding genera of the third section. Their mandibles, however, are covered above by the epistoma, and concealed beneath by the maxillæ,—their exterior side being alone exposed, but without either protruding or presenting the sinuosities or dentations observed in the Rutelæ and other analogous genera. The anterior edge of the labrum is exposed, and is sometimes of the form of a broad reversed triangle, sometimes (and more frequently) of a transverse lamina, emarginate in the centre. The number of the articulations of the antennæ is by no means uniform, and varies from eight to ten. The same observation applies to those of the club, which in several differs even in the sexes of the same species. The ligula is entirely covered by the mentum, or incorporated with its anterior face, and the elytra meet completely along the whole of the dorsal suture,—characters which distinguish our present species from those of the fifth or ensuing section.

*

The family of ANAPLOGNATHIDES of Mr Macleay, and some other genera nearly allied to the preceding, form the first subdivision according to M. Latreille's views. The epistoma is thickened anteriorly, and forms, either alone or with the labrum, a vertical facette in the form of a reversed triangle, the point of which rests on the mentum. This last-named portion is sometimes almost ovoid, densely pilose, with the extremity either rounded or truncated, and without emargination,—sometimes in the form of a transverse square, with the middle of the superior margin prolonged into a tooth, simple or emarginate. The maxillæ of some terminate by a coriaceous or membranous lobe, very hairy, without teeth, or with a very small number, and situate near the middle of the internal border;—those of the others are entirely corneous, resemble mandibles, and are either truncated or obtuse and entire at the end, or terminated by two or three teeth.

In the genera PACHYPUS of Dejean, and AMBLYTERES of Macleay, the mentum is almost ovoid; and in the former the antennæ of the males are composed of only eight joints, of which the last five form the club,—in the latter they consist of ten joints, of which the last three form the club.

In the other genera of this subdivision the mentum forms a transverse square, the centre of the superior margin projecting in the manner of a tooth, entire or emarginate. In the genus ANAPLOGNATHUS of Leach (peculiar to Australasia) there is a sternal projection, and the hooks of the tarsi are entire and unequal. The antennæ are composed of ten joints, and the extremity of the maxillæ is truncated, or obtuse and entire. These insects are

Coleoptera Pentamera.

of considerable size, and of rather brilliant aspect.[1] Here also are placed the genera Leucothyreus of Macleay, and Apogonia and Geniates of Kirby.

* *

A second subdivision of the *Phyllophagi*[2] of Latreille contains the Melolonthidæ of Macleay. In these the labrum is in the form of a transverse plate or leaflet, generally strongly emarginate beneath in its centre, so that when seen in front it exhibits the figure of a reversed or demi-truncated heart. The mentum is as long if not longer than broad, somewhat narrowed anterior to the summit, and either nearly square or heart-shaped; its superior margin is straight, or more or less emarginate or concave, in the middle, but without any tooth-like dilatation. The maxillæ are usually squamous, and armed with several (frequently five or six) teeth. This subdivision is itself capable of a further partition into two groups, the first corresponding to the genus *Melolontha* of Fabricius, as restricted by Illiger and Latreille—the other to the genus *Hoplia* of Illiger. The former continues to bear the name of

MELOLONTHIDES.

Distinguishable by the following general characteristics. The number of complete leaflets of the club exceeds three in several genera. The form of the body is usually thick and massive. The mandibles are strong, entirely or in greater part corneous, and exhibiting at most only a membranous and hirsute appendage, placed in the emargination of the inner side; the superior extremity is strongly truncated, with two or three teeth or angular projections. All the tarsi are terminated by two hooks; the first article of the two anterior being prolonged inferiorly into a hooked appendage. The labrum is usually apparent,—the maxillary teeth robust.

The insects of which this group is composed were included by Linnæus, like all those with which we have been lately engaged, in his extensive genus *Scarabæus*, and they also continued to form a portion of that genus in the works of Geoffroy, Degeer, Schæffer, and other entomologists prior to the time of Fabricius. The last-named author established the genus *Melolontha*, which in its extended signification may be regarded as synonymous with the Melolonthides of Latreille. Were we to follow the prevailing and praiseworthy example of botanists, who bestow upon a *family* the name of the *genus* by which it is most strongly characterized, our present group ought to be denominated *Sericides*, in as far as the type is not formed by *Melolontha vulgaris*, but rather by *M. brunnea* of Fabricius, which now constitutes the genus *Serica* of Macleay. But as it is at all times desirable that families should be named after well-known genera, the designation now adopted is preferable to that which might be derived from the less noted though more characteristic type. The Melolonthides are not often distinguished by brilliant or metallic colouring. Their elytra, of which brown is a characteristic colour, are generally slightly scaly or hirsute. Throughout the entire period of their existence these insects live on vegetable substances, and their ravages are often extremely injurious. The larvæ are very long lived, and sometimes pass three or four years in that destructive state. In cold and temperate climates they are very sluggish, if not torpid, during winter, and descend somewhat deeper into the earth to avoid the effects of frost. The perfect insects feed on leaves,—the larvæ for the most part on roots.

In the genus Melolontha properly so called (from *μηλεα, an apple-tree*, and *ἄνθησις, inflorescence*[3]), see Plate CCXXIV. fig. 29, the antennæ are ten jointed, with the five or seven terminal joints in the males, and the six or four in the females, composing the club. The labrum is thick and strongly emarginate beneath. All the hooks of the tarsi are equal, and terminate in a point entire or simply uni-dentate at their base. The posterior extremity of the abdomen usually ends in a point or style, at least in the males. Of the species of which the antennal club in the male consists of seven leaflets, in the female of only six, we shall here notice the common cockchafer, *M. vulgaris* (*S. Melolontha*, Linn.). The body of this insect is of a pitchy black, with a whitish pubescence; the sides of the abdomen are marked by a range of triangular spots. The elytra are testaceous. The antennæ of the males are much larger than those of the females. (Plate CCXXIV. figs. 21 and 24.) This, though a most abundant insect in England, and over most parts of Europe, is less generally known in Scotland, and is rare in the Edinburgh district. Specimens, however, have been procured in the park of Dalkeith House, in Lanarkshire, at Lorn in Ayrshire,[4] at Raehills and Moffat in Dumfriesshire, and as far north as Glencoe.[5]

We may observe that the existence in the perfect state of the species above named is of very short duration. The life of an individual is supposed not to extend beyond a week, and the entire species during each successive season prevails only for the space of a single month. The male speedily perishes after the sexual union, and the female merely survives for a sufficient time to deposit her eggs in safety. As soon as the latter is fecundated, she digs a hole in the earth of about half a foot in depth, by means of her dentated fore legs. The larvæ which proceed from these eggs are soft, lengthened, of a dingy-white or yellowish colour; they have six short scaly feet, a large scaly head, two antennæ, each composed of five pieces, and nine stigmata on each side of the body. The eyes are not at first visible—being concealed under the skin, which is ere long cast off. These destructive creatures feed upon the roots of various plants. They are most voracious during the summer season. In the course of the autumn they descend into the earth, and pass the winter in a state of profound repose, neither requiring nor desiring food. As soon as the solar rays produce their genial influence in early spring, they ascend within six inches of the surface, and recommence their ravages. They change their skin every year, assume the nympha state in the course of the third autumn after they are hatched, and appear in the perfect state during the ensuing spring or early portion of summer. The beetle, when it first escapes from its cocoon, is pale and soft, and does not venture to leave its subterranean chamber for some time. But ere long it acquires a firm consistence, and crawling to the surface, it expands its wings, and mounting into the air, is henceforward no more a subterranean dweller, but seeks its nourishment among the umbrageous branches of the loftiest trees.[1]

[2] Misnamed (we presume accidentally) *Xylophiles* in the second edition of the *Règne Animal*, t. iv. p. 558.

[3] Μηλολονθη, or Μηλανθη, is a term of frequent occurrence in Aristotle and other ancient authors, and was first applied by Fabricius to the insects of the present genus. It is derived from the words mentioned above, because the insects it denoted either were supposed to be produced from the flowers of fruit-trees, or were accustomed to resort to them for food. This circumstance renders it probable that the *μηλολονθη* of the ancients belonged to the family Cetoniides, as the true Melolonthides are hardly ever seen on flowers; and the description of Eustathius, who says that the animal resembled a wasp, led Mr Macleay to conjecture that it might be the *Trichius fasciatus*, a vernal beetle common in Greece, which might be readily mistaken by a casual observer for one of the Hymenoptera, as it bears a considerable resemblance to some of the members of that order, both in its colouring and mode of flight. Mouffet's investigations led him to a very different conclusion—that the insect was of a metallic green, and referable to the *Buprestides*. The former opinion is greatly the more probable, and accords with the brief notices on the subject found in ancient writers, particularly Hesychius and the scholiast on Aristophanes; but these notices are too imperfect to warrant the determinate application of a word obviously used with considerable latitude of meaning, and intended in all probability to indicate a group or tribe of insects rather than any individual species. (See *Hor. Ent.* p. 78; and Mouffeti, *Theat. Insect.* xxi. 158.)

[4] Professor Rennie, in *Insect Transformations*, 225.

[5] *Ent. Ed.* p. 188.

Although the generality of insects are more destructive in the larva than in any other state, great ravages are occasionally committed even by the perfect insect. It is in relation to the present species that Mouffet records the number of beetles which at one time fell into the Severn as being sufficient to stop the wheels of the water-mills. In the year 1688 they covered the hedges and trees in a district of the county of Galway, in such infinite numbers as to hang in clusters like bees when they swarm. When on the wing they almost darkened the light of day, and produced a peculiar sound by the rustling of their wings. When feeding, the noise of their jaws might have been mistaken for the sawing of timber; and in a very short time the foilage of the trees for miles around was so totally consumed, that at midsummer the country wore the aspect of the leafless winter.[2] "One of the worst of these ravagers," say Messrs Kirby and Spence, "is the grub of the common cockchafer. This insect, which is found to remain in the larva state for four years, sometimes destroys whole acres of grass, as I can aver from my own observation. It undermines the richest meadows, and so loosens the turf that it will roll up as if cut with a turfing spade. These grubs did so much injury about seventy years ago to a poor farmer near Norwich, that the court of that city, out of compassion, allowed him L.25, and the man and his servant declared that he had gathered eighty bushels of the beetle.[3] In the year 1785 many provinces of France were so ravaged by them that a premium was offered by the government for the best mode of destroying them. They do not confine themselves to grass, but eat also the roots of corn; and it is to feast upon this grub more particularly that the rooks follow the plow.[4]"

The scarcity of this species in Scotland saves it from the fate often inflicted in the south, where *spinning a cockchafer* is a favourite amusement among school-boys. When the larger Coleoptera fall upon their backs, they have some difficulty in resuming their natural position,—and in Sweden, according to Sparmann, there is a fond belief among the simpler of the common people, that their sins will be forgiven them if they set a cockchafer upon its legs. If this creed be true, our English youths have much to answer for.[5]

The only other species of the genus which we shall mention is *M. fullo* (Plate CCXXIV. fig. 29), one of the largest of the European Coleoptera. It is sometimes nearly an inch and three quarters long, of a brown or blackish colour, marked with many irregular white spots. The club of the antennæ in the males is remarkably large. This species occurs chiefly on downs along the maritime shores of Europe. It is sometimes captured in England. We have received it from Persia and other eastern countries.

In the genus RHISOSTROGUS of Lat. (formerly AMPHIMALLA of the same author), the species closely resemble the preceding; but the antennæ, consisting of nine or ten joints, have only three leaflets in the club. Such is a well known English insect not yet ascertained to inhabit Scotland, *R. Solstitialis*. In the genus AREODA of Leach and Macleay (Plate CCXXIV. fig. 30) the antennæ have ten articulations, the sternum is corneous, and all the hooks of the tarsi are equal in those individuals presumed to be females, and unequal in such as are regarded as males. The species are brilliantly adorned, and inhabit Brazil. All the preceding phyllophagous genera, it may be observed, with few exceptions, are furnished with ten articulations to the antennæ; but in the following Melolonthides there are only nine. In PHYLLOPERTHA of Kirby (from φυλλον, a *leaf*, and περθω, *to destroy*), the antennæ are only nine jointed. Here we place a species which often appears in prodigious quantities among ferns on commons in many parts of Britain. It is called the Bracken-clock in the north of England—*P. horticola*. It falls into the genus *Anisoplia* of Megerle and Dejean. A larger and much rarer species is *P. Frischii*. It has been found near Montrose. In the genus SERICA[6] of Macleay (Plate CCXXIV. figs. 27 and 28), the joints of the antennæ seem to have been differently computed.[7] All the hooks of the tarsi are bifid. The body is ovoid, arched, with a silky aspect, and changeable reflections. Certain insects, as yet found only in New Holland, form the genus DIPHUCEPHALA[8] of Dejean. Their tarsi are bifid, as in the preceding, but the body is narrow and elongated, and the thorax square. In EUCHLORA of Macleay (Plate CCXXV. fig. 1 and 2), the hooks of the tarsi are unequal, and there is no sternal projection; one of the hooks of the four anterior tarsi is bifid in the males, the body is arched, the epistoma short and transverse.

The second group of this subdivision, or the third and last of the Phyllophagi, is called

HOPLIDES,

and is characterized as follows. The mandibles are small and depressed, and as if divided longitudinally into two parts, of which the internal is membranous, the external corneous; the superior extremity presents no sensible dentations. The labrum is concealed or but slightly apparent. The maxillæ have frequently only small dentations. The body is short, depressed, broad, with the elytra narrowed posteriorly at the exterior side. The last two tarsi are usually furnished with but a single hook. In such as have two hooks to all the tarsi (genus *Dicrania*), the first joint of the anterior tarsi is prolonged inferiorly, and exhibits on the internal side a strong hooked tooth.

---

[1] Some very laborious and beautifully elaborated works have been recently published on the anatomical structure of the Melolonthæ. See more particularly *Considérations générales sur l'Anatomie comparée des Animaux articulés, auxquelles on a joint l'anatomie descriptive du Hanneton*, par M. Straus, 1 vol. in 4to, with plates. Paris, 1828. The illustrious and lamented Cuvier has observed of this production, that it is the only work fit to be compared to that of Lyonnet, *Sur la Chenille du Saule*. M. Dufour has also explained the digestive system of these insects, in the 3d vol. of the *Ann. des Sciences Nat.*; while the muscular economy of the wings and thorax has been described and figured by the accurate Chabrier, in his *Essai sur le Vol des Insectes*. Paris, 1823.

[3] *Phil. Trans.* 1741, 581.

[4] *Introd. to Ent.* vol. i. p. 177.

[5] We may here record that the *Melolontha hippocastani*, Fab. (Olivier, i. 3, a, b, c) was taken by the writer of this article some years ago on the banks of Windermere. It was formerly confounded with *M. vulgaris*, but is distinguished by being rather smaller, shorter, and more convex; the elytra are narrowly margined with black, and the terminal style of the abdomen is rather shorter, and has a slight constriction or neck, which makes the extremity appear broader and more obtuse. It does not seem to be known as British to the English collectors. (See *Entomologia Edinensis*, p. 190, note.)

[6] From σηρικον, *silk*.

[7] Antennæ articulis decem, *Hor. Ent.* 146. Je n'en compte que neuf, *Règne Animal*, iv. 562.

[8] From διφυης, *double*, and κεφαλη, *head*.

M. Leon Dufour, as Latreille informs us, has remarked, that the digestive canal in these insects (at least in such *Hopliæ* as he has examined) is much shorter than that of the Melolonthæ, and rather approaches the same part in the genus Cetonia. The chylific ventricle is smooth and flexuous. The small intestine is shorter than in Melolontha, and often presents an ovoid inflation at its origin. The great intestine is elongated, and destitute of valvular anfractuosities, and the rectum is distinctly marked by an obvious collar. The generative system resembles that of the Melolonthæ.

In the genus Dicrania (Lepel. and Serville, in *Encyclop. Meth.*), besides the characters alluded to above, the body is very smooth, without scales, the scutellum rather large, and there are two strong spines at the extremity of the four posterior tibiæ; the lower extremity of the two hindmost tibiæ is dilated. These insects are natives of Brazil. In the genus Hoplia of Illiger there is only a single hook to the two posterior tarsi (Plate CCXXV. fig. 4). The pairs of the others are bifid and unequal. The extremity of the intermediate and hind tibiæ is as it were crowned by little spines of nearly equal length. The body is generally furnished with minute scales. The epistoma is either almost square or nearly semicircular. The thighs of the two hind legs are moderately enlarged, and the tibiæ are long, straight, and without a hooked tooth at their extremity. *H. farinosa* (Plate CCXXV. fig. 3), one of the most beautiful of European Coleoptera, is a common insect in the south of France. The antennæ are nine-jointed, the body is covered with silvery scales, of a pale but bright and ethereal blue, with a greenish or golden tint beneath. This species, on which a British entomologist gazes with great delight, is common in several European countries, near the banks of brooks and rivers.

Section 5th, Anthobii.[1]

The scarabideous insects of this section also formed a portion of the undivided genus Melolontha, and are nearly allied to the concluding members of the preceding groups. Their paraglossæ, however, or divisions of the ligula, project beyond the upper extremity of the mentum, and the edges of the elytra are somewhat open, or removed from the usual line of the dorsal suture, towards their posterior extremity, which is narrowed to a point, or rounded. The antennæ consist of from nine to ten joints, of which the three last alone form the club in both sexes. The terminal lobe of the maxillæ is often almost membranous, silky, in the form of a pencil,—in others it is coriaceous and dentated along the inner edge. The labrum and mandibles are more or less solid, according as these parts are exposed or covered. These insects live among flowers and the varied foliage of shrubs and trees.

In the genus Amphicoma,[2] Lat. (Plate CCXXV. figs. 5 and 6) the first joint of the antennal club is concave, and encases the others. The mandibles are rounded and curved on the exterior side, without dentation on the inner margin; the antennal mass is globular, the abdomen soft, and all the legs of ordinary size. The epistoma is distinctly margined. The anterior tibiæ have three teeth on their outer edge. The first four articles of the tarsi are strongly ciliated in the males. These singular insects can scarcely be regarded as European, although they do occur occasionally in Greece. They are more frequent in the south of Russia, and in the western parts of the Persian dominions. Comte Dejean informs us that *A. hirta*, Fab. is the female of *A. vulpes* of the same author. *A. vulpecula*, with which we were favoured by M. Faldermann of the Imperial Botanic Gardens of St Petersburg, appears to be also a variety of the first-named insect. The only other genus of this section which we can here notice is Anisonyx of Lat., an example of which is given in Plate CCXXV. figs. 7 and 13.

Section 6th, Melitophili.[3]

In these the body is depressed, usually oval, brilliant, hornless, with the thorax trapeziform or almost orbicular. An axillary piece occupies, in the greater number, the space comprised between the posterior angles and the exterior of the base of the elytra. The anal termination is exposed. The sternum is frequently prolonged in the form of a point or advanced horn. The hooks of the tarsi are equal and simple. The antennæ are 10-articulate, with the last three joints forming the club, which is always foliaceous. The labrum and mandibles are concealed, lamelliform, and nearly if not entirely membranous. The maxillæ terminate in a silky lobe, in the form of a pencil, without corneous teeth. The mentum is usually ovoid, truncated superiorly, or almost square, with the middle of the superior edge more or less concave or emarginate. The ligula is not projecting.

The alimentary tube of these insects, according to M. Dufour, is shorter than in any of the scarabideous family. The chylific ventricle has usually its external tunic covered by very small superficial papillæ, or projecting points. The enlargement which terminates the small intestine is not cavernous, as in the Melolonthæ.[4] The larvæ are said to live in decayed wood. In the perfect state they occur on flowers, and not unfrequently also on the trunks of such trees as exude any fluid.

This section, according to the views of M. Latreille, by which we have already been so long guided, is susceptible of division into three principal groups, corresponding to the genera *Trichius* of Fabricius, *Goliathus* of Lamarck, and *Cetonia* of Fabricius, but reduced and simplified by certain abstractions.

The Melitophili of the first two divisions have no strongly-marked sternal projection; the lateral portion of the mesosternum (or that named *epimera* by M. Audouin) does not generally manifest itself upwardly. The thorax does not increase from before backwards as in Cetonia; nor is the exterior side of the elytra abruptly narrowed or uni-sinuate a little below the humeral angle, as in those insects. A more rigorous character consists in the labial palpi being inserted in lateral grooves of the anterior face of the mentum, so that they are entirely exposed, the sides of the mentum jutting beyond them at their origin, and protecting them behind. In the first two divisions these palpi are inserted beneath the lateral margin of the mentum, or in the margins themselves, in such manner that the first articulations, when viewed from before, do not appear.

---

[1] From ανθος, *a flower*, and βιος, *life*.

[2] From αμφι, *about*, or *on both sides*, and κομη, *hair*, in allusion to the frequent covering with which the species are invested.

[3] From μελι, *honey*, or μελιτοω, *to make honey*, and φιλος, *a lover*.

[4] For other details, especially for such as illustrate the generative system, see *Annales des Sciences Nat*. t. iii. p. 235, and t iv. p 178.

1*st*, TRICHIDES.

In these the mentum is either almost isometrical, or rather longer than broad, and leaves the maxillæ exposed. They correspond, as we have said, to the genus TRICHIUS of Fabricius (Plate CCXXV. figs. 8 and 9), of which we may mention as an example *T. fasciatus*, probably the only British species. It is black, with scattered yellow hairs, the elytra yellowish, with three transverse black bands, interrupted at the suture. It is very rare in Scotland, but is, however, recorded by Mr Curtis as occurring "on the flowers of the thyme, near Loch Rannoch, in July." It was also noticed some years ago by Dr Greville in Glen Tilt, and we saw it taken by Mr Giles Munby, on the southern border of Sutherland, early in the month of August 1833. The dimensions of the female considerably exceed those of the male. The genus, as now restricted, is not very extensive. Dejean enumerates twelve species, several of which are from North America.

2*d*, GOLIATHIDES,

May be distinguished from the preceding by the mentum, which is much longer and wider, and covers the maxillæ. In some the mentum is concave in the centre. The anterior extremity of the epistoma is neither toothed nor horned. Such is the genus CREMASTOCHEILUS of Knock (Plate CCXXV. fig. 10), in which the thorax forms nearly a transverse square; the maxillæ are terminated by a strong tooth, hooked or falciform, with setæ or little spines in place of an inner lobe; the last article of the palpi is very long and cylindrical; the mentum in the form of a widened heart, or of a reversed triangle rounded at the upper angles, without sensible emargination. In others the mentum is in the form of a greatly widened heart, but without a discoidal cavity, its superior edge being emarginate or sinuous. The anterior extremity of the epistoma in the males is divided into two lobes, in the form of obtuse or truncated horns. The thorax is almost orbicular. Such is the extraordinary genus GOLIATHUS of Lamarck (*Cetonia* of Fab. and Olivier), Plate CCXXV. figs. 14 and 16, which contains some of the largest and most striking of coleopterous insects. One of the species which we have represented appears to exhibit some variation in its markings.[1] The same species seems figured by Drury (*Illustrations*, vol. i. pl. 31), who says it was brought from Africa, where it was found "floating dead in the river Gaboon, opposite Prince's Island, near the equinoctial line." The only specimen with which we are now acquainted is that preserved in the Hunterian Museum, Glasgow. Mr Kirby has described two smaller species from Brazil.[2] Other kinds form the genus INCA of modern writers.[3]

3*d*, CETONIIDES.

In this group the sternum is more or less prolonged to an obtuse point, between the intermediate pair of legs; the axillary piece before mentioned is always visible above, and occupies the entire space which separates the posterior angles of the thorax from the base of the elytra; the thorax is usually enlarged posteriorly, and has the form of a triangle truncated anteriorly or at its point. The mentum is never transversal; its superior margin is more or less emarginate in the middle. The terminal lobe of the maxillæ is silky or pencil-shaped. The body is almost ovoid, and depressed. The membranaceous texture of the mandibles and maxillæ of these insects demonstrates, as Mr Macleay has observed, that in the perfect state they live on vegetable juices. Thus *C. morio*, Fab. and doubtless many others, especially of the darker coloured kinds, regale themselves on the sap of wounded trees,—while *C. aurata* and its brilliant allies are only found on flowers.[4] The Cetoniides, though in general gay and ornamental insects, yield in metallic splendour to several species of the genera *Rutela*, *Glaphyris*, and *Anaplognathus*. "Nothing, however, can exceed the beauty and lustre of the polish, or the admirable variety of ornament, with which their elytra are adorned. The larvæ live in the fattest vegetable soils; but notwithstanding the excellent observations of Degeer, much remains to be performed towards the elucidation of this part of their history."[5]

Sufficient data have not yet been collected for the proper elucidation of their geographical distribution, but it appears that many more species exist within than without the tropics. In some the thorax is prolonged posteriorly in an angular form, so that the scutellum disappears. These form the genus GYMNETIS of Macleay (Plate CCXXV. fig. 12). Several species occur in America. In others from New Holland and the East Indies the clypeus is bifid, or armed, in the males, with a couple of horns, and the body is proportionally narrow and elongated, with the abdomen obviously decreasing in size posteriorly. It is even almost triangular in some. The club of the antennæ is elongated. These constitute the genus MACRONOTA of Wiedemann (Plate CCXXV. fig. 15). "Mais toutes ces coupes n'acquerront de la solidité que lorsqu'on aura fait un étude particulière des nombreuses espèces du genre Cetonia de Fabricius."[6]

The European Cetoniæ are provided with a scutellum of ordinary size. *C. aurata* (commonly called the rose-beetle) is well known in many parts of England. It is nearly an inch long, of a brilliant golden green above, with coppery red reflections beneath, and some whitish markings on the elytra. It has been taken in Morayshire by the Misses Dick Lauder, and is also known to have occurred in Dumfriesshire. It is still, however, to be regarded as *inter rariores* of the Scottish species. Dejean's Catalogue contains 125 Cetoniæ, of which the greater part are foreign to Europe. They occur over all the warmer regions of the earth. Java produces several of great beauty, of which *C. Macleayi* is described, and figured by Mr Kirby in his *Century of Insects*.[7] The one which we have represented, *C. Baxii* (Plate CCXXV. fig. 11), is highly prized by collectors.

TRIBE 2D, LUCANIDES.

In this second tribe or principal division of the lamellicorn Coleoptera, which derives its name from the genus Lucanus of Linnæus, the club of the antennæ is composed of leaflets or dentations disposed perpendicularly to its axis, like the teeth of a comb. These organs always consist of ten joints, of which the first is usually much longer than the others. The mandibles are always corneous, generally projecting, and of larger size as well as of different form in the males. The maxillæ in most terminate in a narrow lobe, lengthened and silky; in others they are entirely corneous and dentated. The ligula in the greater number is formed of two small silky pencils, more or less projecting beyond the mentum, which is almost semicircular or square. The anterior legs are generally elongated, with the tibiæ dentated all along their outer edge. The tarsi are terminated by two hooks, equal, simple, with a small appendage, ending in two setæ, between them.[1] These insects compose two sections which correspond to the genera *Lucanus* and *Passalus* of Olivier.

---

[1] See Olivier, *Coléoptères*, No. 6, pl. 5, fig. 33, et pl. 9, fig. 33. We are indebted to Mr Joseph Dalton Hooker for an accurate drawing of the valuable specimen in the Glasgow Museum. We did not receive it till the figure above referred to had been copied by our engraver from Olivier's work.

[2] *Linn. Trans.* vol. xii. p. 407.

[4] *Hor. Ent.* p. 74.

[5] *Ibid.* p. 75.

[6] *Règne Animal*, t. iv. p. 574. We observe a work *On the Family of the Cetoniides*, recently announced in France as preparing for publication, and from which, we doubt not, the entomologist will derive advantage.

[7] *Linn. Trans.* vol. xii.

*

In the first the antennæ are greatly bent or geniculate, smooth, or but slightly hirsute; the labrum small, or confounded with the epistoma; the maxillæ terminated by a membranous or coriaceous lobe, very silky, pencil-shaped, without teeth, or with one at most; the ligula either entirely concealed, or incorporated with the mentum, or divided into two narrow elongated silky lobes, more or less projecting beyond the mentum. The scutellum is placed between the elytra.

In some genera the antennal club consists only of from three to four joints or leaflets. Such are Synodendron[2] of Fab. (Plate CCXXV. fig. 20), Æsalus of Fab., Lamprima of Lat. (ibid. figs. 17 and 22), Ryssonotus, Macleay (*Luc. nebulosus* of Kirby), Philodotus, Macl. (ibid. fig. 19), and Lucanus properly so called (ibid. fig. 18). To the last belongs *L. cervus* (Plate CCXX. figs. 1, 2, 3), the largest and most formidable looking of the British Coleoptera. It inhabits the interior of oaks and beeches for several years before assuming its final transformation, and is by some regarded as the *Cossus* of the ancients, a vermiform larva, long regarded as a delicious food, but not now coveted by the refined epicures of modern days.[3] In other genera of this section the club of the antennæ, as in Syndesus of Macleay, is composed of the seven terminal articulations.[4]

* *

The Lucanides of the second section have the antennæ simply bent, or but slightly geniculate and hairy; the labrum is always exposed, crustaceous, and transversal; the mandibles strong and much dentated, but without any remarkable disproportion of size between the sexes; the maxillæ are entirely corneous, with two strong teeth at least; the ligula, likewise corneous or very hard, is placed in the superior emargination of the mentum, and terminated by three points. The abdomen is supported on a kind of pedicle, bearing the scutellum above it, and separated from the thorax by a neck or obvious interval. These insects form the genus Passalus of Fabricius (Plate CCXXV. figs. 21 and 23), which has undergone subdivision in recent times. In Paxillus of Macleay, for example (fig. 23), the club of the antennæ is composed of five joints, the labrum is very short, the maxillæ have but two teeth, one terminal, the other on the inner side.[5] Mr Macleay restricts Passalus to such species as have only three articulations to the club of the antennæ, as shown by fig. 21. The last-named author here places the genus *Chiron*, which Latreille classes with the coprophagous tribe. All these insects are foreign to Europe, and we believe also to Africa. They are characteristic chiefly of South America, but are also known in New Holland, Java, and the eastern countries of Asia. Madame Merian informs us that the larva of the species figured in her work feeds on the roots of the sweet potato. The perfect insect is well known in sugar-houses.

HETEROMERA.

Five Articulations to the first four Tarsi, and four to the hindmost pair.

All the groups of this, the second primary section of the coleopterous order, feed on vegetable substances. Latreille comprises them under four great families, of which the first two exhibit, by reason of an excrementitious apparatus discovered by M. Dufour, an analogy to some of the pentamerous Coleoptera. Their chylific ventricle is also frequently beset by papillæ. In several of these insects we find the vestiges of another secreting apparatus, of which we have few examples among the Coleoptera, that denominated the *salivary apparatus*. The hepatic vessels, as in the preceding or pentamerous section, with few exceptions, amount to six in number, and have two intestines, distant from each other; at one extremity, according to Dufour, they are inserted by six insulated ends around the collar which terminates the chylific ventricle; at the other they open into the origin of the cæcum by trunks varying in number in different families and genera.

The first general division of the section may be made to contain the first three families. The elytra are generally of a firm and hard consistence, the hooks of the tarsi almost always simple, the head ovoid or oval, susceptible of being sunk posteriorly in the thorax, or sometimes narrowed behind, but not abruptly, and without any neck at the base. Many of these insects are "darklings," that is, lucifugous or light-shunning.

FAMILY I.—MELASOMA.

This group consists of black or ash-coloured species, without mixture or variety of colour, from which circumstance they derive their name.[6] They are for the most part apterous, with the elytra as it were soldered together. The antennæ are partly or entirely granose, almost of the same size throughout, or a little enlarged at their extremity, inserted under the projecting margin of the head, with the third articulation generally elongated. The mandibles are bifid or emarginate at the extremity, and there is a corneous tooth or hook on the inner side of the maxillæ. All the articulations of the tarsi are entire, and the eyes are oblong and but slightly elevated—a character which, according to M. Marcel de Serres, indicates nocturnal habits. Almost all these insects dwell upon the ground, either in sandy soils or under stones, and they are not unfrequent in cellars, stables, the ground floors of houses, and other dark and sombre situations. According to M. Dufour,[1] the insertion of the biliary vessels takes place on the under surface of the cæcum, by means of a single tubular trunk resulting from the junction of two strong short branches, themselves composed of the reunion of three biliary vessels. The bile is yellow, sometimes brown, or even violet coloured. The alimentary tube[2] is long; in the first tribe, that of the Pimeliariæ, three times the length of the body. The œsophagus is long, and leads to a crop, smooth or glabrous externally, more developed among the last-named insects, where it forms an ovoïd sac lodged in the pectus; it is furnished interiorly with folds or longitudinal fleshy columns, terminating in some species, such as *Erodii* and *Pimeliæ*, beside the chylific ventricle, at a valve formed of four principal corneous, oval, and connivent parts. The chylific ventricle is elongated, flexuous or doubled, generally beset with small papillæ or projecting points, and terminates in a small collar, callous within, which receives the first insertion of the biliary vessels. In the genera *Blaps* and *Asida* there is a salivary apparatus, consisting of two floating vessels or tubes, sometimes, as in the latter, perfectly simple, sometimes, as in the former, irregularly branched. The same structure no doubt will be found to occur in others of the family. The texture of the tunics of the alimentary canal has been studied with great care and assiduity by M. Marcel de Serres.[3] The adipose tissue is more abundant in these Heteromera than in the ensuing; and it is probably this provision which enables them, even when transfixed and fastened down by a pin, to live for six months without food—a fact witnessed (we presume accidentally) by Latreille in a species of *Akis.*

---

[1] See our elementary plate (CCXX.) figs. 1, 2, and 3.

[2] From Σὺν, *with*, and Δενδρον, *wood*.

[3] As we have given figures on the plates above referred to, of most of the genera just named, we abstain from entering into the details of their respective characters.

[4] For a description of the singular genus Chiasognathus of Stephens, see the *Cambridge Philosophical Transactions* for 1831.

[5] The insect which we have figured under the name of *Passallus pentaphyllus*, is, we believe, synonymous with *Paxillus Leachii* of Macleay, *Hor. Ent.* p. 106.

[6] From *μέλας*, *black*, and *σῶμα*, *body*.

Our present family, which corresponds to the ancient unrestricted genus *Tenebrio* of the Linnæan system, is subdivided according to the absence or presence of the wings.

TRIBE 1ST, PIMELIARIÆ.[4]

Apterous, the elytra generally fixed or soldered. Palpi almost filiform, or terminated by an article not greatly dilated, and not forming a distinct triangular or securiform mass.

In the genus PIMELIA properly so called,[5] the body is more or less ovoid and oval, with the thorax narrower even at the base than the abdomen, generally convex, without sharp prolongations at the posterior angles, or posterior projection at the præsternum. These insects are proper to the basin of the Mediterranean, to the western and southern parts of Asia, and to Africa.

In the three following genera the body is ovoid, short, arched or gibbous above, with the thorax short, as broad posteriorly as the base of the elytra, and terminated on each side by a sharp angle. The præsternum is dilated posteriorly in the manner of a lamina or point, with its posterior extremity resting on the mesosternum. In ERODIUS, Lat. the last two joints of the antennæ are united, and form a little button-shaped mass. The anterior tibiæ have a strong tooth near the middle of the exterior side, and another on the same side at the end. The mentum is incased (*encadré*) inferiorly, and covers the base of the maxillæ. *E. gibbus*, which is black, the elytra with thin raised lines, occurs in Portugal. In ZOPHOSIS,[6] Lat. the antennæ are almost filiform, or enlarge insensibly towards the end. The anterior tibiæ want the teeth. *Z. testudinarius* is black, the elytra chagrined, and covered on the sides with a whitish powder. It occurs at the Cape. In NYCTELIA, Lat. (Plate CCXXV. fig. 24), the third article of the antennæ is much larger than the preceding, and the following, as well as the ninth and tenth, are almost globular. The base of the maxillæ is exposed. The species are proper to South America.

In the genus HEGETER, Lat. the thorax assumes the form of a trapezium, almost as broad at the posterior margin as the base of the elytra, against which it is applied throughout its breadth. The terminal article of the antennæ is rather less than the preceding. In TENTYRIA of Lat. (*Akis*, Fab.) the thorax is almost orbicular, sometimes narrower than the abdomen, sometimes of the same breadth, but rounded at the posterior angles, and leaving an hiatus between them and the base of the elytra. The terminal article of the antennæ is as large as the preceding. These, as well as the following genera, are peculiar to the warm and western countries of the ancient continent.

The genus AKIS[7] of Fab. (Plate CCXXV. fig. 25) is now restricted to those species in which the thorax is wider than the head, strongly emarginate before, short, its posterior margin widely truncate, and the lateral edges turned up. The antennæ consist of eleven distinct articulations. In EURYCHORA,[8] Thunberg, the body is oval, with acute and ciliated edges, the thorax semicircular, and receiving the head in an anterior notch, the abdomen almost heart-shaped, and the antennæ composed of linear articulations, compressed or angular, of which the third is the longest, and the eleventh indistinct.

The following genera of this tribe differ from the preceding in the mentum, of a square form, not being either emarginate or widened at its upper margin. In TAGENIA of Lat. (*Akis*, Fab.) the thorax is narrow, and either cylindrical, or in the form of an elongated heart, truncate at both ends. The antennæ are almost perfoliate, with the third articulation scarcely longer than the following ones, and the eleventh or last extremely small, and closely united with the preceding. The head is elongated posteriorly, and borne upon a kind of neck or knob. In SCAURUS,[9] Fab. the thorax is at least as broad as the abdomen, almost isometrical. The anterior thighs are strongly inflated, and frequently dentated in the males. The tibiæ are long and narrow. The terminal article of the antennæ is ovoid-conic, and elongated. The species are peculiar to the western countries of the ancient continent, and are confined to its warmer parts. In SCOTOBIUS of Germar, the terminal article of the antennæ is scarcely longer than the preceding, and in the form of a reversed top. The thorax is perceptibly broader than long, and much arched in its lateral margins. These insects are peculiar to South America.

Other insects of this tribe, agreeing with those just named in the entireness of the mentum, are remarkable for the lateral dilatations or tooth-like projections of the thorax. The eyes are more projecting than in the others, and the antennæ are pubescent. The elytra are very unequal. Such is the genus SEPIDIUM[10] of Fab. of which the species are found in the southern countries of Europe, and in Africa.

[10] From Σηπίδιον, *putridity.*

Coleoptera Hetero-mera.

Among the last to which we shall here allude, is the genus TRACHYNOTUS, Lat. (Plate CCXXV. fig. 26), which differs from the preceding in the joints of the antennæ: these are mostly cylindrical, or in the form of an elongated and reversed cone, the last three or four being alone rounded, and either ovoid, turbinated, or hemispherical. The eyes are almost round or oval, entire, or but slightly emarginate, and elevated. The last article of the antennæ is sensibly longer and thicker than the preceding.

In the genus MOLURIS, Lat. *Psammodes*, Kirby (Plate CCXXV. fig. 27), the eyes are narrow and elongated, and scarcely elevated. The thorax is convex, nearly orbicular, emarginate in front, truncated posteriorly, and without angular dilatations on the sides. These insects, in common with those immediately preceding, occur at the Cape.

TRIBE 2D, BLAPSIDES, Lat.

This tribe receives its name from the genus *Blaps* of Fabricius. The maxillary palpi are terminated by an obviously dilated article, triangular or hatchet-shaped. Among other anatomical observations made by M. Dufour in relation to these insects, he states that they are provided with a double excrementitial secreting apparatus, totally different in structure from that of the pentamerous tribes. It consists of two tolerably large oblong bladders, placed altogether beneath the viscera of digestion and generation, closely approximated to each other, with extremely thin parietes, and surrounded by vascular folds, adherent, more or less pursed or turgid, and of which it is difficult to ascertain the precise point of insertion, from the impossibility of unrolling them. The same may be said of the canals destined to the emission of the secreted fluids. They are concealed by a kind of membranous diaphragm, which is applied, by means of a fleshy pannicle, to the last ventrical segment. The fluid flows out laterally, and not from the extremity of the terminal segment: it is of a brownish colour, extremely acrid and irritating, of a peculiar and penetrating odour, and is capable of being thrown to a distance of six or eight inches.

Those in which the body is generally oblong, with the abdomen laterally embraced by the elytra, and in which these parts are frequently narrowed towards the end, and terminate in a tail-like point, form Latreille's first division. The tarsi are nearly alike in both sexes, and without any remarkable dilatation. In the genus ACANTHOMERA, Lat. (Plate CCXXVI. fig. 2), the thorax is almost orbicular, transversal; the abdomen nearly globular; the third article of the antennæ cylindrical, and longer than the ensuing. In BLAPS[1] proper (Plate CCXXVI. fig. 27) the thorax is almost square, and plane or but slightly convex. The abdomen is oval, transversely truncate at the base, more or less elongated. The elytra, for the most part, are narrowed or prolonged to a point, especially in the males. The third article of the antennæ is cylindrical, and much longer than the ensuing; the last is short and ovoid. As an example of this genus (of which there are three British species), we may name a well-known insect, *B. mortisaga* (ibid.) nearly an inch long, of a somewhat shining black, the ends of the elytra forming an obtuse point. It occurs occasionally in pantries, store-rooms, and other parts of houses, especially such as are dirty or neglected. A species called *Blaps sulcata* is said by Fabricius to be eaten by the Turkish women in Egypt, to make them fat. They cook it with butter. On the same authority, it is asserted to be used as a cure for headach and the sting of the scorpion. In SCOTINUS of Kirby (Plate CCXXVI. fig. 9),[2] the thorax is emarginate and dilated at the anterior corners, and the terminal joints of the antennæ are thickened, the two last being confounded together.

Then follow certain Blapsides with an oval and slightly elongated body, and farther distinguished by a sexual difference in the tarsi, the first or the two anterior pair being most dilated in the males, and their inferior surface usually silky, or furnished with a brush. These insects frequent sandy places. Their two anterior tibiæ are generally wider, dilated triangularly at the extremity, and adapted for digging. Here are placed the genera *Pedinus*, *Blaptinus*, &c. of Latreille, Dejean, and other authors.[3]

TRIBE 3D, TENEBRIONITES, Lat.

These differ from the last in being provided with wings. Their body is usually oval or oblong, depressed or but slightly raised, with the thorax square or trapezoidal, and as wide as the abdomen at its posterior extremity. The palpi are larger at their extremity; the last joint of the maxillary palpi has the form of a reversed triangle, or is hatchet-shaped: the mentum is but slightly widened, and leaves the base of the maxillæ exposed. The genus *Tenebrio*, as originally arranged by Fabricius, together with *Opatrum* and *Orthocerus*, serve in this tribe as the types of as many divisions.

1*st*, Those in which the body is oval, with the thorax nearly trapezoidal, arcuated laterally, or forming a semioval truncated anteriorly, wider than the abdomen, at least at its posterior margin, but slightly, if at all, bordered; the maxillary palpi terminated by a securiform joint, or nearly resembling that form; the antennæ insensibly enlarged. Here are placed the genera CRYPTICUS of Lat. and OPATRUM, Fabricius.

2*d*, Those in which the body is narrow and elongated, almost of equal breadth posteriorly, or wider, with the thorax nearly square, and at least almost as long as it is broad; the antennæ forming a thickish club, or abruptly dilated at the extremity. Such are, among others, the genera CORTICUS of Dejean (Plate CCXXVI. fig. 13), ORTHOCERUS, Lat. (ibid. fig. 25), and CHIROSCELIS of Lamarck (ibid. fig. 32).

3*d*, Those of which the body is equally narrow and elongated, with the thorax nearly square, but of which the antennæ are of the ordinary thickness, and not abruptly terminated by a mass or club. In UPIS, Lat. (Plate CCXXVI. fig. 5), the thorax forms a lengthened square; the body is narrow, though not linear; the penultimate joints of the antennæ are lenticular and transversal. In TENEBRIO[4] properly so called (ibid. fig. 23), the thorax differs from that of Upis in being broader than long. *T. molitor* (the species figured) is a well-known insect, which appears in the evening in the least frequented parts of houses. It is likewise found in flour-mills, bakehouses, and among old walls. Its larva, commonly called the meal-worm (ibid. fig. 29), is long, cylindrical, of an ochry yellow, scaly in its texture, and smooth. It lives among bran and flour, and forms a favourite and judicious food for nightingales in the domestic state. It sometimes occurs in the interior of the human body. How it gets there nobody seems to know, but the fact is certain. We have three or four species of the genus in Britain. In a singular genus, named HETEROTARSUS[1] by Latreille (Plate CCXXVI. fig. 30), the penultimate joint of the tarsi is extremely small, in the form of a little knob, and received into a longitudinal groove of that which precedes it, which is itself more dilated, and almost cordiform (ibid. figs. 34 and 36). The only species with which we are acquainted comes from Senegal. It has all the characters of a Tenebrio, with the exception of its remarkable tarsi. At first sight the two anterior seem to consist but of four joints, and the two others of three. See the figures last referred to.

---

[1] From Βλαξ, *slow*.

[2] Owing to the accidental omission, by the engraver, of several figures, which were afterwards inserted in the vacant spaces, some of the subjects of Plate CCXXVI. are by no means in systematic order; but the references in the text will be found correct.

[3] See *Règne Animal*, t. iv. p. 456.

[4] The name refers to the habits of the species, and signifies one that shuns the light.

FAMILY II.—TAXICORNES, LAT.

In this family the small corneous tooth on the inner side of the maxillæ, mentioned in our generalities of the preceding tribes, is wanting. All the species are winged. Their body is generally square, their thorax trapezoidal or semicircular, and either concealing or receiving the head. The antennæ, usually inserted beneath a marginal projection of the sides of the head, are short, more or less perfoliate or granose, and either enlarge insensibly or terminate in a club. The legs are not adapted for running, and all the articles of the tarsi are entire, and terminated by simple hooks; the anterior tibiæ are often broad and triangular. Several males have the head furnished with horns. The greater proportion of these Heteromera occur on tree fungi, or beneath the bark; some live on the ground under stones. M. Dufour has observed an excrementitial secreting apparatus in several genera, and salivary vessels are known to exist in the genus *Diaperis.* The chylific ventricle is beset with little hair-like papillæ.

In some the head is exposed, and never entirely received into a deep anterior notch of the thorax. The latter portion is sometimes trapezoidal or square, sometimes almost cylindrical; its margins, as well as those of the elytra, do not extend perceptibly beyond the body. This division forms

TRIBE 1ST, DIAPERALES, Lat.

In the genus DIAPERIS properly so called[2] (Plate CCXXVI. fig. 1), the maxillary palpi terminate in an article scarcely thicker than the preceding, and nearly cylindrical; the anterior tibiæ, scarcely, if at all, larger than the following, are narrow, almost linear, and feebly dilated at their extremity. Among the ovoid and convex species, with the central portion of the thorax lobate posteriorly, we may name the insect here figured, *D. boleti.* Its body measures about three or four lines in length; it is of a shining black, with three bands of fulvous yellow, transverse and dentated, upon the elytra. It is a well-known British species, not yet observed in Scotland. In LEIODES of Lat. (*Anisotoma* of Fab.) the body is short and convex, and the antennæ terminate in an oval mass of five joints, of which the second is the least. Mr Stephens enumerates above thirty British species, of which *L. arenaria* was lately discovered near Cramond Bridge, Edinburgh.[3] In this tribe are contained several other genera of minute insects, such as *Tetratoma*, Herbst, *Eledona*, Lat. &c.

TRIBE 2D, COSSYPHENES, Lat.

These are analogous in form to the genus *Peltis* of Fab. and to several Nitidulæ and Cassidæ. They are ovoid or sub-hemispherical, and overlapped in their contour by the dilated sides of the thorax and elytra. The head is in some entirely concealed beneath the thorax,—in others it is received or incased in its anterior emargination. The last joint of the maxillary palpi is larger than the preceding ones, and hatchet-shaped. This tribe corresponds to the unrestricted genus COSSYPHUS of Olivier and Fabricius.

In the genus COSSYPHUS properly so called (Plate CCXXVI. fig. 3), the thorax is almost semicircular, exhibits no anterior emargination, and entirely covers and conceals the head. The antennæ are short, terminate abruptly in an oval mass of four articles, chiefly transversal: the second of the whole number and the following ones are almost identical. These insects inhabit the East Indies, the south of Europe, and the north of Africa. In HELÆUS of Lat. and Kirby, the head is received into a deep emargination, or median aperture of the thorax, and is exposed at least superiorly. The antennæ terminate gradually in a narrow elongated club. These insects are peculiar to New Holland. Some other species, proper to South America, of which the body is almost hemispherical, very convex, and of a soft or slightly solid consistence, form the genus NILIO of Lat. At first sight they remind one of Coccinellæ, and of various species of Erotyli.

FAMILY III.—STENELYTRA,[4] LAT.

This family of heteromerous Coleoptera differs from the preceding one chiefly in the antennæ, which are neither granose nor perfoliated. In the greater number the extremity is not thickened. The body is generally oblong, arcuated above, and the legs elongated, as in many other insects. The males, except in their antennæ and general dimensions, resemble the females. Our present species generally are of much more active habits than those we have just left. Many conceal themselves beneath the bark of trees, while most of the others are met with on flowers and foliage. Linnæus referred most of them to his genus *Tenebrio*, and distributed the remainder among the incongruous groups of *Necydalis*, *Chrysomela*, *Cerambyx*, and *Cantharis.* In the first edition of the *Règne Animal*, Latreille combined them under a single genus, that of *Helops;* but a more intimate knowledge of their structure, interior as well as exterior, has since induced him to partition them into five tribes, referable to a corresponding number of the older genera, viz. *Helops*, *Cistela*, *Dircæa*, of Fab. and *Œdemera* and *Mycterus* of Olivier. In *Œdemera* the head is more or less narrowed, and prolonged anteriorly in the form of a muzzle, and the penultimate article of the tarsi is always bilobed,—a character which seems to connect these insects with the weevils, or rhyncophorous Coleoptera. In respect to the digestive canal, and some other considerations, *Helops* and *Cistela* approach the Tenebriones; but in Cistela the chylific ventricle is smooth, and the mandibles entire, and the species affect flowers and leaves, a habit by which they are distinguished from Helops. Most of the Dirceæ possess the faculty of leaping, and the penultimate article of the tarsi, or at least of some of them, is bifid. Some live in mushrooms, others in old wood. They connect on one side with He-

[4] From στενος, *narrow*, and ελυτρον, *sheath*, in reference to the form of the elytra.

Coleoptera Heteromera.

lops, and on the other with Œdemera, and still more with that sub-genus of the same tribe named *Nothus* by Ziegler. These are the principles by which Latreille has been recently directed in his arrangement of the present family.

A certain number (including the first four tribes) have the antennæ approximate to the eyes, and the head not prolonged into a trunk, but terminated at most by a short muzzle.

TRIBE 1ST, HELOPII.

Antennæ covered at their insertion by the margins of the head, almost filiform, or a little larger towards the extremity, generally composed of nearly cylindrical articles attenuated towards the base, and of which the penultimate are frequently a little shorter, in the form of a reversed cone,—the terminal being for the most part nearly ovoid, and the third always lengthened. The extremity of the mandibles is bifid; the last joint of the maxillary palpi is of larger size, and hatchet-shaped, or in the form of a reversed triangle. The eyes are oblong, reniform, or emarginate. None of the legs are adapted for leaping; the penultimate joint of the tarsi, or at least of the hindmost ones, is almost always entire, or not deeply bilobed; the terminal hooks are simple, or without fissure or dentation. The body is for the most part arcuated above, and always of a firm and solid consistence. Such of the larvæ as are known are filiform, smooth, shining, with very short feet, like those of the Tenebriones. They occur in old wood. It is also beneath the bark of ancient trees that we find the perfect insects. The tribe corresponds in great part to the genus *Helops* of Fabricius.

Some have the body almost elliptical, strongly arcuated above, or very convex, with the antennæ at the utmost as long as the thorax, compressed and dilated towards their extremity, like the teeth of a saw; the thorax transversal, plane above, either trapezoidal and widening posteriorly, or almost square; the elytra frequently terminated by a point or tooth. The posterior extremity of the præsternum forms a little salient point, which is received by a forked notch of the mesosternum. Here are placed the genera EPITRAGUS and CNODALON of Lat. and CAMPSIA of Lepelletier and Serville.

In all the other Helopii, the mesosternum exhibits no marked emargination, and the posterior extremity of the præsternum is not prolonged to a point. Here are placed the genera SPHENISCUS of Kirby, ACANTHOPUS of Megerle and Dejean, AMARYGMUS of Dalman, SPHÆROTUS and ADELIUM of Kirby, and HELOPS properly so called. In the last named, most of the joints of the antennæ are nearly in the form of a reversed cone, or cylindrical and attenuated at the base. The thorax is transverse, or scarcely as long as broad, either square, or trapezoidal, or heart-shaped, abruptly narrowed posteriorly, terminated by pointed angles, and always applied exactly to the base of the elytra. Here also are placed the genera LÆNA of Megerle, STENOTRACHELUS, STRONGYLIUM of Kirby, and PYTHO of Latreille.[1]

TRIBE 2D, CISTELIDES.

This is very closely allied to the preceding, but the insertion of the antennæ is not covered. The mandibles terminate in an entire point, or are unemarginate. The hooks of the tarsi are dentated beneath like the teeth of a comb. Several of these insects live on flowers. Their digestive canal is shorter than that of the Helopii, and the chylific ventricle exhibits no papillæ. They correspond to the genus *Cistela* of Fabricius.

In some all the articles of the tarsi are entire. The last joint of the maxillary palpi is simply a little larger, obconical or triangular. In LYSTRONICHUS, Lat., the thorax is thick, narrower than the abdomen, almost orbicular or heart-shaped. The antennæ are thickened towards the extremity. The thighs are clubbed. In CISTELA properly so called, the thorax is depressed, trapezoidal, of the breadth of the abdomen at its posterior margin, or scarcely narrower. The antennæ are filiform, or slightly enlarged at the extremity, and the head is advanced in the manner of a muzzle. In others, such as the genus *Allecula*, Fab., the penultimate article of the tarsi is bilobed, and the last joint of the maxillary palpi much dilated, in the form of a hatchet. The body is generally more oblong.

TRIBE 3D, SERROPALPIDES.

The most remarkable distinction of this tribe, and that from which it derives its name, is the frequent serration of the maxillary palpi, which are likewise large and inclined. The antennæ are inserted in an emargination of the eyes, exposed as in the preceding tribe, and often short and filiform. The mandibles are emarginate or bifid at the extremity, and the hooks of the tarsi are simple. The body is almost cylindrical in some, oval in others, with the head inclined and the thorax trapezoidal. The anterior extremity of the head is not advanced, and the posterior thighs are not inflated. The penultimate article of the tarsi, or at least of the four anterior, is frequently bilobed; and in those in which it is entire the posterior legs at least are adapted for leaping; they are thin, long, compressed, the tarsi small, almost setaceous, with the first article elongated. The anterior are always short and dilated. The genus *Dircæa* of Fabricius forms the type of the tribe. It contains the genera ORCHESIA, Lat., EUSTROPHUS, Illiger, HALLOMENUS, Paykul, DIRCÆA (proper), Fab., MELANDRYA, Fab., HYPULUS, Paykul, SERROPALPUS, Hellw., and CONOPALPUS, Gyll.

TRIBE 4TH, ŒDEMERITES.[2]

This tribe is allied to the preceding by several characters, such as the exposed insertion of the antennæ near the eyes, the bifid extremity of the mandibles, the bilobation of the penultimate article of the tarsi, and the hatchet shape of the terminal joint of the maxillary palpi; but they exhibit other characters, which authorize their separation. The body is elongated, narrow, almost linear, with the head and thorax scarcely so broad as the abdomen; the antennæ are longer than those parts, serrated in some (such as *Calopus*), filiform or setaceous, and composed of long and nearly cylindrical articles, in others. The anterior extremity of the head is more or less prolonged in the form of a small muzzle, and rather restricted behind, with the eyes proportionally more elevated than among the preceding tribes. The thorax is at least as long as wide, and a little narrowed behind. The elytra are linear, or narrowed posteriorly, and are frequently flexible. Latreille regards the species as allied to *Telephorus* and *Zonitis*. M. Dufour has recognised in the Œdemerites the existence of salivary vessels, of a simple nature, flexuous and floating, as well as of a paunch formed by a lateral crop, furnished with a neck or pedicle.

---

[1] For the details of these and other genera of the tribe which we have been unable to do more than name, we must refer the reader to Latreille's *Genera Crustac. et Insect.*; the *Encyclop. Méthod.*; *Linn. Trans.* vol. xii.; Dalman's *Analecta Entomol.*; Dejean's *Catalogue*, and Fischer's *Entomog. de la Russie*.

[2] From οιδιῶ, *I swell*, and μερος, *thigh*.

They are the only Coleoptera in which that character has been observed. These insects, of which the transformations are unknown, are found on flowers and trees. They are all comprised in the old genus *Œdemera* of Olivier.

In some the antennæ are always short, inserted in a notch of the eyes, and simple; the posterior thighs are inflated, at least in one of the sexes; the thorax as broad as the base of the abdomen; and the hooks of the tarsi bifid. Such is the genus NOTHUS of Ziegler, in which the maxillary palpi are terminated by a large elongated hatchet-shaped article. The posterior legs in one of the sexes are very large, and furnished beneath with a strong tooth and two little spurs, near the lower extremity of the tibiæ. The head is not prolonged anteriorly.

In others the antennæ are always longer than the head and thorax, the legs usually of nearly equal size, the thorax narrower than the base of the abdomen, slightly narrowed posteriorly, and the hooks of the tarsi entire. Such are CALOPUS, Fab. SPAREDRUS, Megerle, DYTILUS, Fisch. and ŒDEMERA properly so called (Plate CCXXVI. fig. 4).

TRIBE 5TH, RHYNCHOSTOMA.[1]

In this, which forms the concluding tribe of the Stenelytra, are grouped certain insects, some of which are evidently allied to the preceding, while others in a natural system might be regarded as belonging to the *Rhyncophori.* The head is obviously prolonged anteriorly in the form of an elongated muzzle, or of a flattened trunk, bearing the antennæ at its base, and in advance of the eyes, which are always entire or without emargination.

Sometimes the antennæ are filiform, and the muzzle not enlarged at the base; the thorax is narrowed in front in form of a truncated cone or of a trapezium; the ligula is emarginate, and the terminal joint of the tarsi bilobed. These insects occur on flowers, a habitat indicated by the silky prolongation of the terminal lobe of the maxillæ. Such are the genera STENOSTOMA, Fab. and MYCTERUS, Clairville.

Sometimes the antennæ are terminated by an elongated mass, formed by from three to five terminal joints; the muzzle is very flat, with a projecting angle on each side, anterior to the extremity; the thorax is in the form of a truncated heart, narrowed posteriorly; the ligula and all the joints of the tarsi are entire. These insects dwell beneath the bark of trees, and seem allied to the *Anthribi* of Fabricius. They form the genus RHINOSIMUS of Lat. and Oliv. Those of which the club of the antennæ consists of only three articles, fall under the genus SALPINGUS of Illiger. We have several British species.

The second general division of heteromerous Coleoptera forms

FAMILY IV.—TRACHELIDES.

The head is triangular or heart-shaped, borne upon a kind of neck or abrupt pedicle; the body is usually soft; the elytra flexible, without striæ, sometimes very short, in others slightly inclined. The maxillæ are not unguiculated. The joints of the tarsi are often entire, and the hooks of the posterior ones bifid. The majority of these insects live in the perfect state on various plants, of which they devour the foliage, or suck the nectarous juices. Many, when seized, bend their heads, contract their limbs, and simulate death. Others are extremely active. Latreille divides them into six tribes.

TRIBE 1ST, LAGRIARIÆ.

These have the body elongated, and narrower in front; the thorax either almost cylindrical or square, or ovoid and truncated. The antennæ, inserted near a notch on the eyes, are simple, filiform, or insensibly increasing towards the extremity, generally and at least partially granose, with the terminal article longer than the preceding in the males. The palpi are thickened at their extremity, and the terminal joint of the maxillary is larger, and in the form of a reversed triangle. The thighs are oval and clubbed; the tibiæ elongated, narrow, with at least the two anterior arched. The penultimate article of the tarsi is bilobed, and the hooks of the last are neither incised nor dentated. The tribe is formed of the genus LAGRIA of Fabricius, subdivided in accordance with certain characters detailed in the *Règne Animal*, t. v. p. 52.

TRIBE 2D, PYROCHROIDES,

Approach the preceding in regard to the tarsi and the elongation and restriction of the anterior part of the body,—but the latter is flattened, with the thorax almost orbicular or trapezoidal. The antennæ, at least in the males, are pectinated or plumose—*en panache;* the maxillary palpi are somewhat toothed or serrated, and terminate in an elongated and almost hatchet-shaped article; the labial palpi are filiform. The abdomen is elongated, entirely covered by the elytra, and rounded at the end. These insects are found in woods in spring. The larvæ dwell beneath the bark of trees.

In the genus DENDROIDES, Lat. the antennæ of the males are almost as long as the body, and give off long bearded filaments; in the same sex the eyes are large, and approximated behind. The thorax is trapezoidal, or in the form of a truncated cone; and the body, as well as the legs, is proportionally more elongated. In the genus PYROCHROA properly so called[2] (Plate CCXXVI. fig. 6), the antennæ are shorter and simply pectinated, the eyes distant, and the thorax almost orbicular and transversal.

TRIBE 3D, MORDELLONÆ.

These do not present, either in relation to the form of the tarsi and their hooks, or to that of the antennæ, any constant character in common, but they are easily distinguished from the other Heteromera of the same family by the general conformation of their body. It is elevated, and arcuated; the head is low, the thorax trapezoidal or semicircular, and the elytra either very short, or narrowed, and terminated by a point, as well as the abdomen. Several of these insects approach the Pyrochroides in respect to their antennæ;—others in their maxillæ, the hooks of the tarsi, and their parasitical habits, resemble *Nemognathus* and *Sitaris,* two genera of an ensuing tribe;—but they differ from all of these in their extreme agility, and the firm and solid consistence of their teguments. They formed the old genus *Mordella* of Linn.

Some have the palpi almost of the same thickness throughout. The antennæ of the males are strongly pectinated or fan-like. The extremity of the mandibles offers no emargination. The articles of the tarsi are always entire, and the hooks of the hindmost are dentated or bifid. The middle of the posterior margin of the thorax is always much prolonged backwards, like a scutellum. The eyes are unemarginate. The larvæ of certain species (*Ripiphori*) live in the nests of wasps.

The genus RIPIPHORUS of Bosc (Plate CCXXVI. fig. 7) has the wings extended, and reaching beyond the elytra, which equal the length of the abdomen. The hooks of the tarsi are bifid. The antennæ, inserted near the inner edge of the eyes, are pectinated on both sides in the males,—serrated, or with only a single range of short teeth, in the females. The terminal lobe of the maxillæ is very long, linear, and projecting; and the ligula is also elongated, and deeply bifid. Some naturalists having found in the nest of the common wasp several living specimens of *R. paradoxus*, it has been inferred that they live there in the larva state. M. Farines, however, has observed that the larva of *R. bimaculatus* lives and undergoes its transformations in the roots of *Eryngium campestre*.[1] Here are placed the genera PELOCOTOMA of Fischer, and MYODITES of Lat.

---

[1] From ϱυνχος, *beak*, and στόμα, *mouth.*

[2] From πυϱ, *fire*, and ωχϱος, *yellow.*

Others have the wings always covered by the elytra, which are prolonged nearly to the extremity of the abdomen, and terminate in a point. The posterior margin of the thorax is slightly if at all lobed. The abdomen of the females is terminated by a pointed tall. The eyes are sometimes emarginate. The maxillary palpi are terminated by a large article, in the form of a hatchet or reversed triangle. The extremity of the mandibles is notched or bifid. The antennæ, even in the males, are merely serrated. In MORDELLA properly so called (Plate CCXXVI. fig. 8), the antennæ, of equal size throughout, are slightly serrated in the males. All the articles of the tarsi are entire, and the hooks of the last present beneath one or two small indentations. M. Dufour has observed in a species of this genus two floating salivary vessels, longer than the body. The hepatic vessels have no cæcal insertion,—an exceptive character in the present section. The genus ANASPIS,[2] Geoff. is distinguished from the preceding by the antennæ, which are simple, and gradually enlarged, by the emargination of the eyes, and by the four anterior tarsi, of which the penultimate article is bilobed. The hooks of the last are entire and without sensible dentations.

TRIBE 4TH, ANTHICIDES.

Here the antennæ are simple, or slightly serrate, filiform, or a little thicker towards the end, and most of the articles are in the form of a reversed cone, and nearly alike, except the last (and sometimes also the two preceding), which is larger and oval. The maxillary palpi are terminated by a securiform club. The penultimate joint of the tarsi is bilobed. The body is narrow anteriorly, with the eyes entire or slightly emarginate. The thorax is sometimes in the form of a reversed oval, narrowed and truncated posteriorly, sometimes divided into two knots, in others semicircular. Certain species are found on plants of different kinds, but the majority occur upon the ground. They run with great swiftness, and their larvæ have been supposed to be parasitical. They compose the genus NOTOXUS[3] of Geoffroy, which Latreille divides into SERAPTIA, STEROPIS, and NOTOXUS properly so called.[4]

The two concluding tribes of this family, and of the heteromerous section, exhibit certain characters in common, such as the termination of the mandibles in a simple point, the palpi filiform or simply a little longer at their extremity, but never either clubbed or securiform, the abdomen soft, the elytra flexible, and in most instances blistering or vesicatorial, and, with few exceptions, the articles of the tarsi entire, and the hooks of these parts generally bifid. They are all herbivorous in the perfect state, but many are parasitical, while larvæ, in the dwellings of other tribes.

TRIBE 5TH, HORIALES.

These differ from the ensuing, or Cantharidiæ, in their hooks, which are dentated, and each accompanied by a serrated appendage. The antennæ are filiform, not longer than the thorax; the labrum is small, the mandibles strong and projecting, the palpi filiform, the thorax square, and the two posterior legs very robust, at least in one of the sexes. The tribe is composed of the genus HORIA of Fabricius (Plate CCXXVI. fig. 10). These insects inhabit the intratropical regions of India and America. The lamented Lansdown Guilding has published figures and a short history of *H. maculata*.[5] It deposits its eggs in the nest of a wood-gnawing bee (*Xylocopa teredo*), and the larvæ, when hatched, are supposed to devour the food deposited in the ligneous chambers for a very different purpose by the parent bee. "Forsan," says Mr Guilding, "dum larva cibum apibus præparatum avide consumit, hospes fame perit." It is often so.

TRIBE 6TH, CANTHARIDIÆ.

This tribe is distinguished from the preceding by the hooks of the tarsi, which are deeply divided, and appear as if double. The head is generally large, broader, and rounded posteriorly. The thorax is usually narrowed behind, and approaches the form of a truncated heart; in some it is almost orbicular. The elytra are often somewhat inclined laterally, or tectiform, and rounded. These insects counterfeit death when seized, and several of them exude a yellow caustic liquor, of a penetrating odour, from the joints of their antennæ; but no peculiar apparatus for the production of that secretion has yet been ascertained. Many kinds are highly serviceable in the formation of blistering applications. They were all included originally in the old genus MELOE of Linnæus, now greatly subdivided. The anatomical observations of M. Dufour, and the extremely interesting researches of M. Bretonneau of Tours, on the vesicatorial properties of this tribe of insects, have enabled Latreille to arrange them in what he regards as a natural order,—not greatly differing, however, from that which he had previously adopted. M. Bretonneau has ascertained that the genus *Sitaris* is not vesicatorial,—and M. Dufour has found that these same Heteromera possess only four biliary vessels instead of six, the amount by which other insects of the tribe are characterized. That genus also resembles *Zonitis* in its general organization, while the latter is itself closely allied to *Cantharis*. The series of groups adopted by Latreille is also in harmony with the progressive changes in the form of the antennæ.

In some these organs are composed in both sexes of only nine articulations, of which the last is large, and in the form of an ovoid head; those of the males, as well as their maxillary palpi, being very irregular. The body is depressed. Such is the genus CEROCOMA of Geoff. The species make their appearance during the summer solstice, and frequently in great numbers on the same spot. They frequent the flowers of the wild chamomile, milfoil, &c. *Meloe Schæfferi* of Linn. of a bluish green, with the antennæ and legs wax yellow, may be mentioned as an example.

In all the others the palpi are identical and regular in both sexes. The antennæ have generally eleven articulations, and when they offer one or two less they terminate regularly in a club. The body is thickish, and the elytra somewhat inclined.

[5] *Linn. Trans.* vol. xiv. part ii. p. 315.

In some the antennæ, always regular and granose in both sexes, sometimes appear to be composed of only from nine to ten joints, and are not longer than half the body; they occasionally terminate in an arcuated club, or are obviously enlarged at the extremity; while in others they form from the second joint a short cylindrical or almost fusiform stem. They constitute the genus *Mylabris* of Fabricius. Such of them as have the two or three last joints of the antennæ united, at least in the females, and forming an abrupt, thick, ovoid, or button-shaped club, the extremity of which does not extend beyond the thorax, and in which the total joints are only from nine to ten, form the genus Hycleus of Lat. Such, again, as have the antennæ proportionally longer, and offering in both sexes eleven distinct and well-divided articulations, gradually enlarging, or terminating by degrees in an elongated club, of which the terminal joint, very distinguishable from the preceding, is large and ovoid, belong to the genus Mylabris properly so called (Plate CCXXVI. fig. 11). The species we have here represented is the *M. chicorii.* It is more than half an inch long, black, pilose, with an almost round yellowish spot on the base of each elytron, and two transverse and indented bands of the same colour, one near the centre, and the other nearer the extremity. The antennæ are black. This insect, unknown in Britain, is occasionally found as far north as the vicinity of Paris, but it is much more common in the south of France, and other meridional parts of Europe. Its blistering qualities are quite as active and efficient as those of the true *Cantharis* or Spanish fly; and in Italy it is employed for the same purposes, mixed up with the latter, or even used alone. *M. pustulatus* is used by the Chinese.

In the other Heteromera of this tribe the antennæ, always composed of eleven very distinct joints, are almost of equal thickness throughout, or rather more slender towards the extremity, and frequently much longer than the head and thorax. They are irregular in several males. In Meloe properly so called (Plate CCXXVI. fig. 12), the antennæ are composed of short and rounded joints, the intermediate of which are the largest, and sometimes so disposed that these parts in the males exhibit an emargination or crescent-like form. The wings are wanting, and the elytra, oval or triangular, with a portion of the inner margins crossing each other, only partially cover the abdomen, especially that of the females, which, as often happens, is extremely voluminous. According to Dufour, the crop of these insects may be considered as a true gizzard, being furnished internally with callous and anastomosing plicæ, and separated from the stomach or chylific ventricle by a valve formed of four principal pieces, each of which results from two hollow cylinders placed back to back, and tridentated posteriorly.

All the species of the genus Meloe are awkward and mis-shapen, and of sluggish movements. They are found either crawling slowly and heavily along the surface of the earth, or on plants of humble growth. They feed on leaves, and when handled, an oily fluid of a yellow or reddish colour flows from the joints of their legs. Latreille suspects that these insects are the *Buprestides* of the ancients, to which were attributed such destructive effects on cattle, when inadvertently swallowed by the latter. The genus seems characteristic of the European continent and islands. Eight or nine species occur in Britain; and of the twenty-one species enumerated by Dejean, the whole are European. Mr Kirby however possesses a specimen taken in North America by Professor Peck. They are all characterized by dark or sombre colours. They are most frequent in spring and autumn, and occur in fields and pathways, preferring, it is said, a sunny situation and a sandy soil. In some districts of Spain they are employed along with Cantharides, or in their room. They are also used by farriers.[1] The females, when filled with eggs, become greatly dilated, and in that condition much exceed the males in size. An individual of the former sex observed by Goëdart, and fed by him with the leaves of anemone and ranunculus, laid 2212 eggs between the 12th of May and the 12th of June, besides about as many more which were thrown aside uncounted. It effected this laying at two separate periods, placing the extremity of its abdomen in a hole which it had formed in the earth, and depositing the eggs in packets. These are of a yellowish colour, and resemble grains of sand pressed together. The larvæ are long, cylindrical, garnished with scattered hairs, composed of eleven nearly equal segments, besides the head, which is oval, and provided with two eyes, and a pair of longish antennæ. They have six legs, of rather large size compared with the length of the body, which is terminated by two long bristle-like appendices. Their larvæ are supposed by some ingenious observers to be parasitical on the bodies of winged insects. Degeer having remarked that a strong resemblance existed between the larvæ of Meloe, and a small insect which he found adhering to *Eristalis intricarius*, he placed two domestic flies among the former, and found that they were speedily adhered to by the larvæ, which stuck to them pertinaceously, and caused their death in two or three days. Bees are also subject to their attacks; and MM. Lepelletier and Serville are said to have recently confirmed the observations of Degeer, by breeding these parasites from the eggs of Meloe. "On the other hand," says Mr Curtis, "Mr Kirby is disposed to think that his *Pediculus Melittæ* (P. Apis, Linn.?) is not the larva of Meloe; and M. Leon Dufour has even formed them into a *genus* under the name of *Triungularis andrenetarum;* and a figure of one is given in the thirteenth volume of the *Annales des Sciences Naturelles.*"[2] M. Latreille seems to adopt the opinion of their parasitical nature; and the facts, so far as known, are well stated by M. Walkenaer, in his *Memoires pour servir à l'Histoire Naturelle des Halictes.*[3] The digestive system of the genus Meloe, with other anatomical details, has been illustrated by M. Dufour;[4] and we are indebted for a monograph of the British species to Dr Leach.[5]

All the ensuing genera of the tribe are provided with wings, and elytra, of the ordinary structure, covering longitudinally the back of the abdomen. In the genus **CANTHARIS**, Geoff. (Plate CCXXVI. fig. 14), all the joints of the tarsi are entire, the thorax almost ovoid, a little elongated, and restricted anteriorly, truncated posteriorly. The second joint of the antennæ is much shorter than the following, and the last of the maxillary palpi is sensibly larger than the preceding. The head is a little broader than the thorax. The antennæ of the males are sometimes irregular, and even semi-pectinated. The name of Cantharis is extremely ancient, and has been received in a variety of acceptations. Aristotle did not apply it to any particular insect, but to various Coleoptera.[1] Linnæus made use of the term to designate a great genus of the same order, which, however, did not include the true Cantharis, which he placed in *Meloe*. Geoffroy substituted the name *Cicindela*, already otherwise employed, for that of Cantharis, and placed in the latter the genuine Spanish fly. Fabricius placed it in his genus *Lytta*, which corresponds to Cantharis of Geoffroy. The latter, however, amidst all these revolutions of names, appears to have maintained its ground, and to have been the most generally adopted.

---

[1] In regard to these insects we may further observe, that Dr Leach was informed by Mr Hunneman that the species called *M. variegatus* is highly prized in Germany as a medicine, being considered as a specific in hydrophobia. For this purpose it is taken by slipping a hair round its neck, and suspending it till dry; the oily secretion first thrown out being preserved, as in that the chief virtue is supposed to exist. Mr Hunneman adds more particularly, that the late king of Prussia, Frederick the Great, purchased the nostrum from the discoverer for a valuable consideration, as a specific against the bite of a mad dog. According to the recipe, twenty-five of these insects that have been preserved in honey, are, with two drachms of powdered black ebony, one drachm of Virginia snake-root, one ditto of lead filings, and twenty grains of fungus sorbi, to be reduced to a very fine substance; the whole, with two ounces of theriaca of Venice (and, *if necessary*, a little elder root), to be formed into an electuary! (See *Linn. Trans.* xi. p. 245.)

[5] *Linn. Trans.* xi. p. 35 and 242.

The Cantharides properly so called have an elongated and almost cylindrical form. The history of the most noted species, *C. vesicatoria*, commonly called the Spanish fly (fig. 14), is still somewhat doubtful, so far as concerns our knowledge of its transformations. Neither Degeer nor Geoffroy ever saw the larva. Those who suppose themselves to have seen it say that it feeds on various roots, and is metamorphosed in the earth,—an observation which accords with the usually sudden appearance of the perfect insect, the unexpected apparition of which has sometimes given rise to the belief that they migrated from more southern regions. It is described by Olivier as consisting, in its early state, of thirteen segments, soft, of a yellowish-white, with six short scaly feet,—the head rounded and flattish, and furnished with two short filiform antennæ. The mouth consists of a pair of tolerably solid maxillæ and four palpi. The medicinal uses of this now celebrated beetle are universally known, but its connection with the sanitory art is not traceable to a remote antiquity; for the Cantharis of the ancients was certainly not the same as the Spanish fly, and is even supposed to have belonged to a different genus. According to the testimony of Pliny and Dioscorides, who affirm that the best Cantharides are such as are marked with transverse yellow bands, it becomes evident that their species was the *Mylabris chicorii* already mentioned, which in China is used for epispastic preparations down to the present day. The insect of the European laboratories, *C. vesicatoria*, is of a beautiful golden green, with black antennæ. The males are less than the females, and there exists in general a great variety of size among different individuals. These insects are very common in France,[2] Italy, and Spain. The greater proportion employed in commerce come from the last-named country, and hence their common name. Their collection requires precaution on the part of those who are employed in that office, both with a view to guard against injurious accidents, and for the proper preservation of the objects themselves. They are killed by means of vapour of vinegar, and completely dried after they are dead. The following is the plan of procedure: In the course of the month of June the natives place extended cloths or sheets beneath the trees on which the Cantharides occur, and make them tumble down by beating all the branches. When they have obtained a considerable quantity, they either put them into a hair sieve, which they place over the vapour of vinegar, or into a fine cloth, which they dip repeatedly in a vessel containing diluted vinegar. They are then allowed to dry under the shade of some loft or granary, being placed on hurdles covered with cloth or paper, and stirred occasionally with a stick, or with the hand protected by a stout glove. When thoroughly dry they are packed into vessels of wood or glass, which are afterwards carefully and tightly closed. These little processes being properly attended to, the insects retain their blistering qualities for a length of time.

The chemical analysis of Cantharides has been made by numerous experimentalists, who appear, however, to have confined their researches rather too exclusively to the Spanish fly. Had they studied with equal assiduity the genera *Meloe* and *Mylabris*, and even *Carabus*, *Coccinella*, and several *Tenebriones*, they would have discovered in these also an analogous or identical principle, less active perhaps in its nature, but for that very reason susceptible of being employed with greater advantage in special cases. Thouvenet, Fourcroy, Beaupoil, Orfila, and especially Robiquet, have arrived at some remarkable results. The latter has demonstrated the existence of a particular substance, on which he has bestowed the name of *Cantharadine*, and which may be characterized as white, crystalline, insoluble in water, soluble in boiling alcohol, in ether, and in oils. It is the seat of the vesicatorial or blistering property, which does not therefore reside in the green oil, nor in the black insoluble matter, nor in the yellow matter soluble in alcohol and in water,—the other ingredients of which analysis has demonstrated the presence. This discovery, though important in a scientific point of view, has produced no alteration in the practice, which proceeds effectually enough upon the old experience, that when the substance of the insect is reduced to powder, mixed up with some fatty matter, and applied to the surface of the body, it immediately proceeds to action, and detaches the outer skin from the dermis with great rapidity. It is also used for several other purposes.[3] Naturalists are acquainted with many other species of Cantharis besides the Spanish fly. Of these we may mention *C. Syriaca* of Olivier, which occurs in Syria and the south of Europe, and the *C. dubia* of the same author, found in the southern provinces of France, Italy, the Levant, and Siberia. In the United States a species, described by Fabricius under the name of *vittata*, is employed for medicinal purposes. It is found in great abundance among potatoes.

The remaining genera of the tribe are **ZONITIS**, Fab. **NEMOGNATHUS**, Lat. **GNATHIUM**, Kirby, and **SITARIS**, Lat.

TETRAMERA.

Four Articulations to all the Tarsi.

The numerous and important groups which constitute this, the third primary section of the coleopterous order, are all vegetable feeders. The larvæ have very short

---

[1] *Hist. Animal*, lib. iv. cap. 7.

[2] Latreille observes that they appear in France about the period of the summer solstice, and that they occur more particularly on the ash and lilac, on the leaves of which they feed. They diffuse around them a peculiar and highly penetrating odour.

[3] See *Annales des Sciences Nat.* ix. p. 31; and *Diction. Class. d'Hist. Nat.* iii. p. 156.

Coleoptera Tetramera.

feet, and in many even these seem wanting, or are replaced by mammillæ. The perfect insects occur among flowers and plants. Latreille divides them into seven families. The larvæ of the first four or five most commonly live concealed in the interior of plants, and are generally destitute of feet, or have these organs extremely small; many attack the hard or ligneous portion of their dwelling. These Coleoptera are the largest of their section.

FAMILY I.—RHYNCHOPHORA.[1]

This numerous and widely extended family, so remarkable for the beauty of its South American species, is easily recognised by its more or less extended muzzle, terminated by a mouth, of which the parts, from their peculiar structure and position, are not easily determined without the aid of microscopical examination and dissection. The abdomen is generally of a bulky form, the antennæ geniculate and clavate, and the penultimate joint of the tarsi almost always bilobate. In many tribes the posterior thighs are dentated. The body of the larvæ is oblong, and resembles a small white worm, exceedingly soft. The head is squamous or scaly, and the feet are either wanting or mammillæform. They live by gnawing the various parts of plants. Many dwell exclusively in the interior of fruits and seeds, and do great damage to the farmer, grain-dealer, and horticulturist. Some, such as the Brachyceri, are supposed to live beneath the ground, and to feed on roots.

The muzzle in this richly adorned family differs essentially from the *rostrum* of the hemipterous species. It is in fact merely a prolongation of the head, and not composed of the parts of the mouth, as in the last-named order. This prolongation, however, exerts an influence over the alimentary tube, the œsophagus being thereby somewhat prolonged, and—as we find to be the case in the truly suctorial tribes—there is also a provision of salivary glands.

We have little detailed information regarding the internal structure of the Curculionidæ. Two species (*Attelabus betuleti* and *Cryptorhynchus lapathi*) have been examined and described by Ramdhor.[2] In both of these the alimentary canal was moderately long, the stomach partially shaggy, and the small intestine inversely claviform. In other respects, however, they differed materially. There was no crop or gizzard in the former, the stomach was fringed on each side, except at its upper extremity, with a series of small cæca or shags, and there were three pair of bile-vessels; in the latter the gullet was dilated into a crop, which included a gizzard of singular and exquisite construction; for, though so minute as scarcely to exceed a large pin's head in size, it was found to be provided internally with more than four hundred pairs of teeth, moved by an infinitely greater number of muscles. A transverse section of this gizzard represented two concentric stars, with nine rays each, the object of this structure being the comminution of the timber which the insect has to perforate, and probably devour. The stomach was very slender, but dilated in the middle into a spherical vesicle; and only two pairs of bile vessels were observable.[3]

It may well be supposed, that in a family consisting of not much less than three thousand ascertained species, many diversities occur both in habit and external structure. The antennæ are sometimes straight, but more frequently have an angular bend. They are inserted either towards the extremity of the muzzle when that organ is short, or nearer the centre, or even towards the base, in the long snouted species. The number of the articulations of the antennæ varies in certain genera from six to ten; but eleven is the more usual number, or even twelve, if we count the false or terminal article. The body is generally narrowest in front, with a large abdomen covered by very hard elytra. The tarsi are very frequently garnished beneath with short hairs. None of the species are carnivorous in any degree; but even in the perfect state they are sometimes extremely noxious, when they happen, as they sometimes do, to occur in great abundance. They tap the buds and leaves of trees, and of several cultivated vegetables, and feed upon their juices.

TRIBE 1ST, BRUCHELÆ, Lat.

Labrum apparent, anterior elongation of the head short, broad, depressed, and in the form of a snout. Palpi very visible, filiform, or larger at the extremity. These insects compose the old genus *Bruchus*, Linn. They are subdivided as follows.

---

[1] Since the publication of the first edition of the *Règne Animal*, considerable attention has been bestowed on this difficult family. Messrs Germar and Schœnherr, more particularly, have devoted their time to its elucidation; and the latter author (in his *Curculionidum Dispositio Methodica*, Leipsic, 1826) gives a hundred and ninety-four genera, exclusive of sub-genera. He divides the Curculionidæ, in accordance with the straightness or geniculation of their antennæ, into two great sections, the *Recticornes* or *Orthocera*, and *Fracticornes* or *Gonatocera*. The recent observations of M. Leon Dufour on the internal structure of these insects seem to strengthen the propriety of that classification. The species of the latter section are furnished with salivary vessels, which are wanting in those of the former. In Latreille's recent reconstruction of Schœnherr's arrangement, the Recticornes compose four tribes—the *Bruchelcs*, the *Anthribides*, the *Attelabides*, and the *Brentides*. In the first two the labrum and palpi are very visible; these palpi are filiform or larger at the extremity; they are small and conical in the two other tribes, as in all the following Rhynchophora. The Fracticornes form a fifth tribe, viz. the *Curculionites*. These are divided into the *Brevirostres* and the *Longirostres*, terms which bear relation to the place of insertion of the antennæ. In the former these organs are attached to the extremity of the muzzle, or on a line with the base of the mandibles,—while they are placed further back, or nearer the head, in the latter. The genera of the *Brevirostres* are arranged in three subtribes, viz. *Pachyrhyncides*, *Brachycerides*, and *Liparides*,—corresponding to the genera Curculio, Brachycerus, and Liparus of Olivier; the last sub-tribe comprising also some Lixi of that author. The relative size and form of the mentum, the mandibles, the presence or absence of wings, the direction of the lateral sulci of the proboscis, in which the first joint of the antennæ is partly lodged, the length of that joint, and the proportions and forms of the thorax—these and other secondary considerations furnish the characters of the various groups. The *Curculionites Longirostres* are divided into two principal sections, in accordance with their habits, and the composition of their antennæ. These consist, in the *Phyllophagi*, of not fewer than ten joints, the last three of which, at least, form the terminal club. But among the *Spermatophagi* the antennæ never consist of more than nine joints, of which the last or the last two form the club. The legs of the Phyllophagi are sometimes contiguous and sometimes remote. Those in which they approach each other are divided into four tribes:—the *Lixides* (Lixus, Fab.), the *Rhynchænides* (Rhynchænus, Oliv.), the *Cionides* (Cionus, Clairv.), and the *Orchestides* (Orchestes, Illig.). The *Spermatophagi*, again, form three principal sections or sub-tribes:—the *Calandræides* (Calandra, Clairv., Fab.), the *Cossonides* (Cossonus, Clairv.), and the *Dryopthorides* (Dryopthorus, Schœn., Bulbifer, Dej.). These latter lead to the *Hylesini*, Fab., and other Xylophagi. (See *Règne Animal*, t. v. p. 69.) A great proportion of the European Curculionidæ are most accurately described by Gyllenhal in his *Insecta Suecica*. Mr Kirby's paper on the genus *Apion* (Linn. Trans. vol. iv.) is also deservedly esteemed. The reader will find a critical and expository treatise on this family by Latreille, under the term RHYNCHOPHORES, of the *Dict. Class. d'Hist. Nat.* t. xiv. p. 584 He may also consult Germar's *Insectorum Species Novæ*, and the continuation of Illiger's *Magazin für Insectenkunde*. The British species are described, with their usual skill, by Messrs Curtis and Stephens. The latter, in the second edition of his *Nomenclature*, enumerates above 500 indigenous species. The Scottish kinds are described in our *Entomologia Edinensis*. We see, from our recent correspondence, that about 3000 species of this great family are now known to naturalists.

[2] *Abbildungen zur Anatomie der Insecten.*

[3] *Introduction to Entomology*, vol. iv. p. 107.

Those species of which the antennæ are clavate, or very obviously enlarged at their extremity, with the eyes unemarginate, and which appear to have five articulations to the four anterior tarsi, form the genus Rhinosimus, which Latreille, in accordance with its tarsal characters, formerly placed among the Heteromera, but which other natural affinities connect more closely with the following genus. Those of which the antennæ and eyes resemble the last, but which present only four tarsal articulations, compose the genus Anthribus[1] of Geoffroy and Fab. (Plate CCXXVI. fig. 16), to which Latreille adds the *Rhinomacers* of Olivier. These insects are generally found on old wood, although some occur on flowers. In the genus Bruchus properly so called[2] (Plate CCXXVI. fig. 17), the antennæ are filiform, frequently serrated or pectinated. The eyes are emarginate. The anus is exposed, and the hind legs are frequently very large. These species deposit their eggs in the yet tender germs of our leguminous plants, of our most valuable grains or palms, coffee, &c., where the excluded larvæ occasion infinite damage. The perfect insect detaches a portion of the epidermis in the form of a cap, and, on issuing, produces those circular holes so often seen on peas and beans. Such is a small species called *B. pisi* (see the figure last referred to), an insect which has been known to occasion great injury in North America. A very large species, the *B. Bactris* of Linn. occurs in Cayenne, where it feeds on the fruit of *Cocos guinensis*. It is named *Counana* by the natives. The genus Rhœbus of Fischer is distinguished from the preceding by flexible elytra and bifid hooks to the tarsi. The genus Xylophilus of Bonelli is characterized by clavate palpi.

In the other tribes there is no apparent labrum. The palpi are very small, inconspicuous to the naked eye, and of a conical form. The anterior prolongation of the head represents a beak or trunk.

*

Sometimes the antennæ are straight or not geniculate (*Orthoceri*), inserted on the rostrum, and consist of nine or ten joints.

Those in which the three or four last joints are united into a club form

Tribe 2d, Attelabides, Lat.

They gnaw the leaves and tender parts of plants. Most of the females roll up these leaves into a tube or trumpet, in which they deposit their eggs,—thus forming a proper nidus for their offspring. The different proportions of the trunk, the mode of its insertion, the nature of the tibiæ, and the form of the abdomen, have given rise to the formation of several genera, such as Apoderus,[3] Attelabus,[4] Rhynchites,[5] and Apion.[6] The first is very strongly marked. The head is narrowed behind, or presents a neck-like prolongation, and unites with the thorax by means of a rotule. The muzzle is short, thick, enlarged at the end, a character common to the Attelabi properly so called; but in them, as well as in the other two genera, the head enters into the thorax up to the eyes, and the snout is elongated in the form of a proboscis. In Rhynchites the latter is somewhat widened at the end, and the abdomen is nearly square. In Apion, of which Mr Stevens enumerates ninety-one species as indigenous to Britain, the snout is not widened at the end, and frequently terminates in a point. The abdomen is large or inflated.[7] Here also are placed the genera Rhinotia and Eurhinus of Kirby,[8] and Tubicenus of Dejean (*Auletes*, Schœn.[9]).

Those in which the antennæ are filiform, or in which the terminal article alone forms the club,—in which the muzzle, often longer in the males than in the females, and differently terminated, is always borne in advance,—of which the proportions of the body are usually much lengthened, and in which the penultimate article of the tarsi is bilobed, form

Tribe 3d, Brentides, Lat.[10]

In the genus Brentus properly so called (Plate CCXXVI. fig. 15), the body is linear, and the antennæ filiform or slightly enlarged towards the extremity, and composed of eleven articulations. There is only one species of Brentus found in Europe, the *B. italicus*, which lives beneath the bark of trees, and generally, according to Savi the younger, of Pisa, in the same domicil with a certain species of ant. They are numerous in South America, and occur there also beneath the bark of trees. The genus Ulocerus, Schœn. resembles the preceding in general form, but the antennæ have only nine articulations, the last of which forms a little club. The last of this tribe is constituted by the genus Cylas, Lat. in which there are ten articulations to the antennæ, the last of which forms an oval club. The thorax seems divided into two knots, of which the posterior, forming the pedicle, is the smallest. The abdomen is oval.

* *

Sometimes the antennæ are distinctly geniculate (*Gonatoceri*), the first articulation being much longer than the following. These form the genus *Curculio* of Linn. or

Tribe 4th, Curculionites, Lat.

These seem naturally divisible into two lesser groups, according as the antennæ are inserted near the extremity of the proboscis (*Brevirostres* or *Brachyrhynchi*), or further back, either towards the centre, or near the base (*Longirostres*, or *Mecorhynchi*); "mais il n'est pas facile," says Latreille, "de bien determiner leurs limites, et plusieurs genres sont très-ambigues sous ce rapport."[11]

A. Brevirostres.

In the genus Brachycerus,[12] Fab. all the joints of the tarsi are entire, and without brush or pellet beneath. The antennæ are short, not much bent, and present externally only nine joints, the last of which forms the club. These insects are destitute of wings, and their body is very scabrous or uneven. They are characteristic of Southern Europe and of Africa, live on the ground, in sandy soils, and appear very early in the spring. The women of Ethiopia use one species as a sort of amulet, passing a string through its body, and hanging it around their necks.[13]

---

[1] From ανθος, *flower*, and τρίβῶ, *I destroy*.

[2] From βρύκῶ, *I gnaw*.

[3] From απο, used to augment the sense of the word with which it is used, and δερε, *the neck*, which is much prolonged.

[4] From αττω, *to leap*, and λαβε, *seizure*. The name was originally applied by Aristotle to an orthopterous insect.

[5] From 'ρυγχος, *rostrum*.

[6] From ἄπιον, *a pear*, which the insects somewhat resemble in form.

[12] From βραχὺς, *short*, and κερας, *horn*.

[13] Caillaud, *Voyage au Fleuve Blanc*.

In the genus Curculio, Fab. almost the whole of the under parts of the tarsi are furnished with short stiff hairs forming pellets, and the penultimate article is deeply divided into two. The antennæ are composed of eleven articulations, or even of twelve, if we count the false one by which they are sometimes terminated. The last form the club. This splendid and extremely numerous genus, although greatly restricted by Fabricius, compared with its vast extent in the system of Linnæus, has been still more circumscribed by authors of the present day. An enormous accession of species having been discovered and described, these have been arranged by Germar, Schœnherr, Megerle, Dejean, and others, into a corresponding variety of generic groups, partly for the sake of convenience, and partly (though not entirely) because the nature of the subjects required such systematic modifications. Latreille's observations have led him to form these Curculiones into two principal divisions.

1*st*, Those in which the mentum, more or less widened superiorly, and more or less orbicular, occupies the entire breadth of the cavity of the mouth, and wholly or nearly conceals the maxillæ,—and in which the mandibles have no very sensible dentations, or merely exhibit a slight sinus underneath the point. The generic groups are as follows. In Cyclomus the tarsi (as in genus *Brachycerus*) are unprovided with brushes, and the penultimate articulation is entire, or very slightly notched, without distinct lobes. In this genus Latreille would comprise those named *Crytops*, *Deracanthus*, *Amycterus*, and *Cyclomus* of Schœnherr. The tarsi of all the others are furnished with brushes beneath, and the penultimate joint is deeply bilobate. Some are apterous. In Curculio properly so called (Plate CCXXVI. fig. 18), the lateral sulci of the proboscis are oblique and directed inferiorly. The anterior legs differ little in their proportions from the following ones. The genus, even thus restricted, comprises an immense number of groups, raised by Germar and Schœnherr to the rank of genera, "dont les caractères," says Latreille, "sont peu importants et souvent très-equivoques."[1] He thinks that at most only those should be detached of which the antennæ are proportionally longer. Among such as have short antennæ, the thorax longitudinal, and forming a truncated cone, the shoulders salient, and of which recent writers have formed the genera *Entimus*, *Chlorima*, and others, we find many noted South American species, of considerable size and exquisite beauty, and which, considered all in all, may be regarded as the most splendid examples of the coleopterous order. Such, for example, is *C. imperialis*, commonly called the diamond-beetle, which (may the scientific reader pardon the digression), inclosed in its little box, and covered by a microscope, has so often exhibited to the wondering gaze of youth hues more gorgeous than are ever seen in after days, when no glass, however potent, can dispel the mists which gather around whatever seemed the brightest and most beautiful of earthly things. The species just named is of a brilliant golden green, with two black longitudinal bands upon the thorax. There are several ranges of impressed or hollow spots upon the elytra, of a beautiful and sparkling green, with intervals of black, presenting the appearance of innumerable emeralds incased in gold and ebony. Such also is *C. regalis*, an insect still of great value, of which in former days a single specimen once sold in Paris for L.23 sterling. It is a good deal less than the diamond-beetle, of a bluish green, with extremely brilliant gold and copper bands upon the elytra. It is found in St Domingo and the island of Cuba. Many others, of almost equal beauty, will occur to the recollection of those who have inspected an extensive collection of foreign insects, and the specific names of *fastuosus*, *sumptuosus*, *nobilis*, and *splendens*, sufficiently attest the unfeigned admiration of the lovers of nature, of that bright attire which distinguishes these favoured creatures.[2] The genus Leptocerus[3] differs from the preceding in having the two anterior legs larger than the following, with the thighs thick, the tibiæ arcuated, and the tarsi often dilated and ciliated. The antennæ are usually long and slender. The thorax is almost globular or triangular, and is scarcely exceeded in width by the abdomen. These insects are very abundant in Brazil, and several analogous species are found in the Isles of France and Bourbon. Some inhabit Africa. Another genus, that of Phyllobius,[4] comprehends likewise winged species, but in which the grooves of the sides of the proboscis are straight, short, and consist only of a simple fossette. Several of these are extremely common in Britain. Along with the preceding, Latreille combines the genera *Macrorhynus*, *Myllocerus*, *Cyphicerus*, *Amblirhinus*, and *Phytoscapus*, of Schœnherr.

Those Brevirostres in which the penultimate joint of the tarsi is bilobate, but which are apterous, and always destitute of a scutellum, form other sub-genera, such as *Othiorhynchus*, *Omias*, *Pachyrhynchus*, *Psalidium*, *Thylacites*, *Syzygops*, and others.

2*d*, Those in which the mentum is narrowed, and, not occupying the whole of the cavity of the mouth, leaves the jaws exposed on either side. The mandibles, too, are evidently dentated. The club of the antennæ is frequently formed of the last five or six joints.

Some have scarcely more than two teeth to the mandibles. The labial palpi are distinct. The club of the antennæ, rather abrupt, does not commence, except from the eighth or ninth articulation, and is not elongated and fusiform. The body, though frequently oblong, is not of a uniform figure. Several are apterous, with the tarsi unfurnished with pellets, and their penultimate article feebly bilobed. Such is the genus Myniops of Schœnherr, with which Latreille combines *Rhytirrhinus* of that author. Several, likewise apterous, have, like most of the Rhynchophori, the under surface of the tarsi furnished with pellets, and the penultimate article deeply bilobed. They compose the genus Liparus, Lat. which comprises several genera of Schœnherr. Such as are winged form two additional genera,—that of Hypera, Germar, in which the tibiæ have either no hook at their extremity, or but a very small one, and that of Hylobius,[5] in which the hook at the internal extremity is very marked. Among the former, *H. tamarisci* (the type of the genus *Coniatus* of Schœnherr) rivals in its colours the most beautiful of the exotic species; among the latter we may name a well-known Scottish insect, *H. abietis*, Linn. (*Cur. pini* of Marsham[1]).

---

[1] *Règne Animal*, t. v. p. 78.

[2] Even among our native Curculionidæ there are many species, though of small size, yet of exquisite beauty. The genera *Polydrusus* of Germar, and *Phyllobius* of Schœnherr, frequent the foliage of trees and of herbaceous plants. They excel most of the indigenous Coleoptera in brilliancy of colouring,—produced by a covering of minute scales, the body itself being dull and opake. These scales vary in shape, being often rounded and adpressed to the surface, at other times narrower, and having the appearance of hair. The prevailing colours are green or silvery-green, golden, and coppery, of various shades and different degrees of resplendency,—a considerable range of variation being observable even among individuals of the same species. Green, however, is by far the most common colour, and is no doubt intended to contribute to the preservation of the insect by assimilating it to the objects by which it is usually surrounded. (See *Entomologia Edinensis*, p. 253.)

[3] From λεπτος, *slender*, and κερας, *horn*.

[4] From φυλλον, *a leaf*, and βιος, *life*.

[5] From ὕλη, *wood*, and βιος, *life*.

Others have from three to four teeth upon the mandibles, the mentum abruptly narrowed near its upper extremity, and truncated, the palpi very small or imperceptible. The antennæ terminate gradually in an elongated fusiform club. The body has in most an analogous form. Olivier placed these insects in the genus Lixus, from which, in fact, they do not greatly differ. They compose the genus Cleonus, as constituted by Latreille.

B. Longirostres.

In this, the second group of the tribe Curculionites, the antennæ are inserted beyond the origin of the mandibles, and often near the centre of the proboscis, which is usually elongated. It comprises, with the exception of a few species, the genera *Lixus*, *Rhynchænus*, and *Calandra* of Fabricius. In the two former the antennæ are composed of at least ten articulations; they frequently consist of from eleven to twelve, of which at least the last three form the club.

The genus Lixus of Fab. (Plate CCXXVI. fig. 19) almost resembles *Cleonus* in the organs of manducation, the elongated fusiform club of the antennæ, the long and narrow form of the body, and the curvature of the tibiæ. *L. paraplecticus* (the species figured) is nearly linear. Its larva lives in the stem of *Phellandrium aquaticum*, and is alleged by Linnæus to occasion *paraplegia* among horses. The disease, as well as the plant, is called Staikra by the Swedes. The transformations of the insect are described by Degeer. Another species, *L. odontalgicus*, is a reputed cure for toothach.

The genus Rhynchænus of Fab. does not present an equal uniformity of character among its constituent parts, and has therefore been numerously subdivided. We shall mention a few of the modern groups.

*

In some the legs are contiguous at the base, and there is no sternal groove for the reception of the proboscis. Of these a certain number never leap; their antennæ are composed of eleven or twelve joints, and their body is furnished with wings. Such are the genera Tamnophilus,[2] Bagous (small insects found in marshes), Brachypus,[3] Balaninus[4] (remarkable for the great length of the proboscis), Rhynchænus properly so called, and Sybines. Along with these may be placed Myorhinus of Schœnherr, and other genera, distinguished from the preceding by being apterous. In the genus Cionus the antennæ consist of from nine to ten joints. The body is usually very short, and almost globular. The ensuing differ from those above named in having very thick posterior thighs, which give the faculty of leaping. Those in which the antennæ are inserted on the proboscis form the genus Orchestes[5] of Illiger (Plate CCXXVI. fig. 20); those in which they originate between the eyes, that of Ramphus[6] of Clairville.

* *

In other Fabrician Rhynchæni the legs are remote at the base, and the sternum frequently exhibits a more or less extended cavity for the reception of the muzzle, and even sometimes for that of the antennæ. Those in which that sternal groove does not exist are formed by Latreille into two sub-genera, Amerhinus and Baridius. Those in which it does exist have been formed by Schœnherr into a great many genera, reduced to the following by Latreille, viz. Camptorhynchus, Centrinus, Zygops, Ceutorhynchus, Hydaticus, Orobitis, Cryptorhynchus, and Tylode.[7]

The last of the Longirostres have generally nine articles at most to the antennæ, of which only the last or the last two form the club, which is characterized by a coriaceous epidermis and spongy extremity. These insects live, at least in their larva state, on grain and ligneous substances. They form the great genus *Calandra*, now subdivided into the six following smaller groups.

The first two are apterous, the penultimate joint of the tarsi is bilobed, the antennæ are geniculate and inserted at a short distance from the middle of the trunk. In the first, genus Anchonus of Schœnherr, the antennæ exhibit nine articulations anterior to the short ovoid club, which is formed by the tenth, and perhaps by two others intimately united with it. In the second, Orthochætes of Germar,[8] it is the eighth joint which seems to form the club, although it is probably also of a compound structure. The four following are provided with wings. In the first three the tarsi, in accordance with the almost universal and implied character of the great *tetramerous* section of which they form a part, are all composed of four articulations, of which the penultimate is bilobed. In Rhina, Lat. (*Lixus*, Fab.), the antennæ are strongly geniculate, and inserted near the middle of a straight projecting proboscis,—their eighth joint forming a greatly elongated and almost cylindrical club. The anterior legs are longer than the others, at least in the males. Of this genus we may mention as an example a well-known and singular-looking insect, found in Cayenne and Brazil, called *R. barbirostris*, on account of a thick yellowish-brown beard which envelopes the proboscis of the male, and gives it somewhat the appearance of a bottle-brush. The female wants this kind of garniture on her snout, and she was consequently mistaken by Illiger for a separate species, and named *R. verrirostris*. In the genus Calandra properly so called, the antennæ, likewise strongly geniculate, are inserted near the base of the proboscis,—the eighth joint forming an ovoid or triangular club. The insects of this

---

[1] It frequents the Scotch fir, and is common in the Edinburgh district, as well as throughout Scotland. It seems to occur pretty frequently over our southern borders, is more sparingly distributed in Cumberland and the adjoining counties, and, becoming gradually scarcer as we advance, is regarded as a rare insect in the southern parts of England. The imperfect description of this species given by Linnæus, who appears, in some of his works, to confound it with another insect, has rendered it rather difficult to identify his *Cur. Abietis*, and its synonyms have consequently become perplexed. From an inaccurately named specimen in the Linnæan cabinet, Marsham was led to believe that it was the *Cur. pini* of that illustrious observer, and he accordingly described it under that name in his *Entomologia Britannica*. Neither Paykul nor Fabricius appear to have formed accurate views of its characters,—the latter, in his *Species Insectorum*, regarding it as a sexual variety of an insect which in fact belongs to a different genus. The larva inhabits the wood of the Scotch fir, often proving very destructive to young plantations of that tree. The manners of the perfect insect are well described by Linnæus in his peculiar style: "Tarde incedit, arcte apprehendit, tenaciter adhæret, ore frustra cutem mordere tentat captivus."

[2] From ταμνω, or τέμνω, *to cut asunder*, and φίλος, *a lover*.

[3] From βϱαχυς, *short*, and πους, *foot*.

[4] From βαλανινος, *produced from an acorn*.

[5] From ὀϱχηστής, *a leaper*.

[6] From ϱαμφος, *the beak of a bird*.

[7] For their characters, see *Règne Animal*, t. v. p. 86–7.

[8] *Insectorum Species Novæ*, p. 302.

genus are but too well known for their destructive attacks upon grain, and are included with many others under the vague name of *weevil.* The most noted and injurious species *C. granaria* (*Cur. granarius*, Linn.), is fortunately rare in Scotland, and probably in most other northern countries. But in France and other continental territories it is extremely injurious. This little creature measures about a couple of lines in length, and is generally of a pitchy red, smooth, the thorax deeply punctured. The elytra are rather narrower than the base of the thorax, and do not cover the extremity of the abdomen. They are marked with deep striæ, punctured in the bottom. The legs are ferruginous. It is not in the perfect state that this destroyer commits its ravages. The season for the deposition of the eggs, and the periods of transformation, vary to a certain extent with the temperature of particular seasons; but generally in the south of France, as we are informed by M. Audouin, the female commences her maternal labours about the month of April, and continues them till the autumn. She first buries herself in a heap of grain, to the depth of some inches, and then commences to pierce their envelope, probably by means of a little dart concealed beneath the lower portion of the proboscis. The envelope is then raised, and a small hole bored, either in an oblique direction, or parallel with the surface of the grain. A single hole is made in each grain, and a single egg is laid in each hole, after which the opening is closed by a glutinous matter, so nearly resembling the colour of the grain, that it is extremely difficult to discover which is in a sound state, or which contains the germ of an insidious foe. The injured grains may, however, be detected by their floating when immersed in water, as well as by their feeling lighter when fingered by a practised hand. The egg thus laid is soon hatched, and gives birth to a very minute, white, soft, elongated worm, composed of nine segments, with a rounded corneous head, furnished with two strong mandibles, by means of which it daily enlarges its dwelling, fills its own stomach, and empties the purse of the farmer or grain-merchant. Having attained the term of its increase, it is transformed into a nymph, remains in that state for eight or ten days, and is transformed into a perfect insect, which, piercing the envelope of the grain, ere long produces in its turn a numerous progeny. The influence of temperature, so general on insect life, is effective on this noted *Charanson de blé;* but from forty to forty-five days may be stated as an average term between the union of the sexes and the reproduction of the perfect insect. When the old and unphilosophical belief prevailed of the spontaneous generation of the lower tribes of animal life, it was thought sufficient to say that these weevils were "engendered in the grain by humidity." At an after period it was thought by some who called themselves "observers"—(men of the same class with those who settle all natural phenomena by a paragraph in a newspaper, which they sign "Scrutator"),—that the perfect insect laid her eggs in the green ear, from whence, when the fields were ripe for harvest, they were transported to the stores of the granary. The accurate and inimitable Leeuwenhoeck (*Continuatio Epistolarum*, p. 56) dispelled these errors, and taught us the truth of nature, of which he was ever so great an interpreter. As each larva consumes only a single grain, we may form some idea of their power of increase, from the vast quantity sometimes destroyed. According to the calculation of Degeer, a single pair will produce (among themselves and their descendants), in the course of a season, *twenty-three thousand six hundred* individuals; so that, we may add, a few hundred weevils flying through the grating of a granary, and settling among its treasured heaps, might in the course of four or five months devour or destroy between *one and two hundred millions* of grains. Various modes have been suggested by economists and men of science to stay the progress of these destroyers. We are not sure that any of them have been found very efficacious. The most approved is the following: When the principal body of grain is suspected, let a small heap be placed apart in a corner, and the rest repeatedly stirred about and disturbed. The weevils, which love repose and a quiet life, will leave their usual domicils, and seek about for more peaceful dwellings. An instinct, which the foresight of man in this instance renders unavailing, induces them to settle on the smaller heap, and the shoveling of the main body being continued for some days, a vast number may be thus got quit of. Boiling water is then thrown upon the congregated insects, which have sought refuge in what they deemed a place of safety. As this process destroys only the perfect insects, and not the eggs or larva, neither of which care about being stirred up with any pole, however long, it must be employed during the earliest heats of spring, and before the laying of the eggs. It is said to succeed best when (whatever the principal store consists of) the decoy heap is formed of barley, which, it seems, is a favourite food of weevils. Reduction of temperature by ventilation has also been recommended, as tending to diminish their productive powers; and M. Clement thinks that dryness produced by lime may prove useful, by its tendency to destroy the eggs.[1] Of the larger kinds of Calandra we may mention *C. palmarum*, an insect known to all who have looked into collections of foreign Coleoptera, among which it is extremely common. It is a large species, measuring about an inch and a half in length. It occurs in South America. The larva (figured by Mad. Merian[2]) is named *ver palmiste* by the colonists. It lives in the heart of palm trees, and undergoes its transformations in a cocoon formed of the fibres of those lofty and plume-supporting plants.[3] It is fried and eaten as a great delicacy, both by Indians and Creoles. "C'est probablement," says M. Audouin, "quoi qu'en ait dit Linné, cette même larve, et non celle du Cossus, dont les Romains étaient si friands, et qu'ils nourrissaient avec de la farine." We cannot well see how this could be, unless the new world was known to the Romans, or Italy to the palmist worm. We believe, however, that the Cossus of the ancients was indeed the larva of a beetle (probably of one of the long-horned kinds), and not of a lepidopterous nocturnal insect, or *Cossus ligniperda*, commonly so called.

Our two remaining genera are Cossonus of Clairville and Dryopthorus of Schœnherr (*Bulbifer*, Dejean). In the former the antennæ, scarcely longer than the head and muzzle, have eight joints anterior to the club. They are thick, and inserted towards the middle of the muzzle. In the latter the antennæ have only six joints, of which the last forms the club. In regard to the tarsi the genus presents an anomalous character, and one which, if strictly applied to the definition of the section, would exclude it from the tetramerous families. They present five articulations, none of which are bilobed.

[2] *Insectes de Surinam*, pl. 48.

[3] The palm which this insect most affects seems to be one of small size. According to Madame Merian, it grows to the height of a man, and is cut off when it begins to be tender, is cooked like a cauliflower, and tastes better than an artichoke. In its centre live innumerable quantities of larvæ, which at first are as small as a maggot in a nut, but afterwards grow to a very large size, and feed on the marrow of the tree. They are laid on the coals to roast, and are regarded as a "most pleasant food."

FAMILY II.—XYLOPHAGI.[1]

These exhibit a head formed in the ordinary way, without any obvious muzzle, or trunk-like projection. The antennæ are thicker at their extremity, or perfoliated from their base, always short, and consisting in a great number of less than eleven articulations. The joints of the tarsi are usually entire, but with the penultimate enlarged and heart-shaped in some, in which case the antennæ always terminate in a club, either solid and ovoid, or trifoliate, with the palpi small and conical. These insects mostly live and feed in wood, from which habit they derive their family name; and their larvæ are often destructive to timber, in consequence of the ramified perforations which they form in all directions beneath the bark. They frequently so abound in forests of fir and pine, as to render in a few years an immense number of trees entirely useless for all the purposes of human art. Others are extremely injurious abroad to the olive plantations, while several feed on mushrooms. Latreille divides them into three sections.

1*st*, Those of which the antennæ have at most ten joints, and are sometimes terminated by a strong club (generally solid, in others composed of three elongated leaves), sometimes form from their base a cylindrical and perfoliated club; the palpi conical. The anterior tibiæ of the greater number are dentated, and armed with a strong hook; and the tarsi, of which the penultimate article is frequently bilobed or heart-shaped, are capable of being bent or folded on them.

Some have very small palpi, the body convex and rounded above, or almost ovoid, with the head globular, sunk into the thorax, and the antennæ terminated by a solid or a tri-lamellar club, preceded by at least five joints. These Xylophagi compose the old genus SCOLYTUS[2] of Geoffroy, which Linnæus did not distinguish from *Dermestes*. They now form the genera HYLURGUS, Lat., HYLESINUS,[3] Fab., SCOLYTUS proper (Plate CCXXVI. fig. 22) of Lat., CAMPTOCERUS, Dejean, PLOIOTRIBUS and TOMICUS, Lat., and PLATYPUS, Herbst.[4] Of many of these each female deposits numerous eggs, and 80,000 wood-eating larvæ have been calculated to inhabit a single tree.

Others have the palpi large and obvious, and of unequal length. Their body is depressed, narrowed in front; their antennæ are sometimes apparently only bi-articulate, with the last joint very large, flattened, almost triangular or ovoid, and sometimes consist of ten joints, entirely perfoliate. The labrum is large. The elytra are truncated, and the tarsi short, with all the articles entire. These insects are all exotic, and compose the genus PAUSSUS of Linn.[5] It has been greatly increased in recent times, and is now divided into several genera.[6]

2*d*, Those of which the antennæ consist of only ten articulations, and of which the palpi, at least the maxillary ones, do not taper gradually to a point, but are of equal thickness throughout, or dilated at the extremity. The joints of the tarsi are always entire. The constituent groups form two principal genera, according to the mode in which the antennæ are terminated. Thus, in BOSTRICHUS the three terminal joints form a perfoliated club. These insects however form four lesser genera, viz. BOSTRICHUS proper (e. g. *Dermestes capucinus*, Linn.) Plate CCXXVI. fig. 24, PSOA, Fab., CIS, Lat., and NEMOSOMA, Desmarets. The second principal genus, called MONOTOMA, is distinguished by the solid and button-like form of the tenth articulation of the antennæ, and is likewise further divisible into four minor genera,—SYNCHITA, Helw., CERYLON, Lat., RHYZOPHAGUS, Herbst, and MONOTOMA proper.

3*d*, The Xylophagi of the third division have eleven very distinct articles to the antennæ; the palpi vary, being filiform or thickened at the extremity in some, more slender at their termination in others. All the joints of the tarsi are entire. Among the LYCTI the club of the antennæ consists but of two joints. They form the genera LYCTUS[7] proper, DIODESMA, Meg., BITOMA, Herbst. Among others the last three or four joints of the antennæ form the club, or the last alone is larger than the preceding ones. In the MYCETOPHAGI, Fab. the mandibles are covered, or project but little. In Latreille's arrangement they form the following seven genera:—COLYDIUM and MYCETOPHAGUS (proper),[8] Fab., TRIPHYLLUS, Meg., MERYX, Lat., DASYCERUS,[9] Brongniart (Plate CCXXVI. figs. 26 and 28),[10] SYLVANUS, Lat., and LATRIDIUS, Herbst. The species of the last-named genus are exceedingly minute, none of them exceeding a line and a half in length, and several being scarcely half that size. They occur in houses, vaults, cellars, &c. and are not unfrequently found beneath the bark of trees. From their habits they are called lurking beetles (Lauerkäfer) by the Germans. Their generic name (from *Lateo?*) has probably the same signification. The larvæ are somewhat egg-shaped and elongate, consisting of twelve segments of a dirty white colour, the antennæ and legs clear as water, with a black line along the back, and a tuft of hairs on the sides of each segment. They live for a longer or shorter period in this condition, according to the state of the temperature and supply of food; the usual time is from four to six weeks. They then change into nymphs of a transparent white, with brownish-yellow eyes, from which, in about fourteen days, emerge the perfect insects.[1] We have about a dozen species in Britain.[2] In the TROGOSITÆ,[3] Olivier and Fab. (*Platycerus*, Geoffroy), the mandibles are entirely exposed, salient and robust. The body is generally elongated, narrow, and depressed. In some of these the antennæ are shorter than the thorax, or at most of equal length, and terminate in a compressed club, a little toothed or serrated, and formed by the three or four last articulations. The ligula is entire. In TROGOSITA proper the mandibles are shorter than the head, and crossed. The maxillæ have but a single lobe. *T. mauritanica* (*Tenebrio mauritanicus*, Linn.), about four lines in length, blackish above, light brown beneath, with striate elytra, occurs in nuts, bread, and beneath the bark of trees. The larva, known in Provence under the name *Cadelle*, attacks grain. Here follow the genera PROSTOMIS of Lat. and Passandra of Dalman.

[2] From σκολίοτης, *tortuosity*.

[3] From ὑλη, *wood*, and σινω, *I injure*.

[4] For their characters see *Règne Animal*, t. v. p. 91–2, and the works there referred to.

[5] The genus *Paussus* did not exist in the twelfth edition of the *Systema Naturæ*, but was published by Linnæus in a separate dissertation in 1775. Only a single species appears to have been known at that period (Mr Westwood now describes above twenty), and another was added in 1796 by Dr Adam Afzelius, then residing at Sierra Leon (*Linn. Trans.* vol. iv.). The etymology of the name is supposed by Afzelius to be from the Greek παυσις, signifying a pause, cessation, or rest; for Linnæus, now old, infirm, and sinking under the weight of age and labour, saw no probability of continuing any longer his career of glory. "He might therefore," adds Dr Shaw, "be supposed to say, 'Hic meta laborum,' as it proved in reality, at least in regard to insects—Pausus being the last he ever described." (*Gen. Zoology*, vol. vi. p. 43.) It was literally, in the language of Young, "An awful *pause*, prophetic of his end."

[6] See an elaborate and learned Essay *On the Paussidæ, a family of Coleopterous Insects*, by Mr J. O. Westwood, *Linn. Trans.* vol. xvi. p. 607.

[7] From λυγτος, *smooth or polished*.

[8] From μυκετος, *moss*, and φαγος, *eating*.

[9] From δασυς, *hairy*, and κερας, *horn*.

[10] We have figured the type of the genus, *D. sulcatus*, on the plate above referred to. This singular little insect was discovered by M. Alex. Brongniart on a fungus in the forest of Montmorency. It is extremely small, and it is difficult to count the articulations of the tarsi, even with the aid of a good microscope. These parts consist, however, of only three articulations (see fig. 31), which would remove the genus from the tetramerous section, were it not allied to the above genera by other natural characters. The first two joints of the antennæ (see fig. 21) are globular, the following ones very small, capillary and pilose, and the last three or four also pilose and globular.

FAMILY III.—PLATYSOMA.[4]

This group of tetramerous Coleoptera approaches the preceding so far as relates to the internal structure, the tarsi, and the habits; but the antennæ are of equal thickness throughout, or more slender towards their termination. The mandibles are always projecting; the ligula is bifid or emarginate; the palpi are short, and the body depressed and lengthened, with the thorax nearly square. These insects are found beneath the bark of trees, and are reduced by Latreille to the CUCUJI of Fabricius, which he distinguishes as CUCUJUS proper (Plate CCXXVI. fig. 21), DENDROPHAGUS, Gyll. and ULEIOTA, Lat.

FAMILY IV.—LONGICORNES.

The insects of this family, which in the system of Linnæus formed the genera *Cerambyx*, *Leptura*, and *Necydalis*, have the under surface of the first three articles of the tarsi garnished with brushes, the second and third being heart-shaped, the fourth deeply bilobed, with a little swelling or nodule resembling an articulation at its base.[5] The ligula, borne upon a short and transverse mentum, is generally membranous, heart-shaped, emarginate or bifid,—in others corneous, and forming the segment of a very short and transverse circle. The antennæ are filiform or setaceous, generally at least as long as the body, sometimes simple in both sexes, sometimes serrated, pectinated or flabelliform, in the males. The eyes of a great number are reniform, and surround the antennæ at their base. The thorax is in the form of a trapezium, narrowed anteriorly in such as have the eyes rounded, entire, or slightly emarginate; in which case also the legs are long and slender, and the tarsi lengthened. M. Leon Dufour has remarked that the Longicornes, in regard both to the alimentary tube and the disposition of the hepatic vessels, generally resemble the Melasoma, and, contrary to the opinion of M. Marcel de Serres, he denies the existence of a gizzard. The alimentary canal, usually beset with papillæ, is preceded by a crop, which is smaller and less distinctly marked in Lamia and Leptura, the concluding genera.

The larvæ of almost all the Longicornes live in the interior or beneath the bark of trees. They are either apodal, or provided with very inconspicuous legs. Their body is soft, whitish, largest anteriorly, with a squamous head, furnished with strong mandibles, but without any other projecting parts. They are extremely destructive to the larger forest trees, piercing them to a considerable depth in all directions. A certain number gnaw the roots of plants. The abdomen of the female, in the perfect state, is terminated by a tubular and corneous oviduct. Several species produce a sharpish sound by rubbing a portion of the thorax against the pedicle which attaches the base of the abdomen. Lister calls this sound *querulous*, while Dumeril compares it to the braying of an ass. It is on account of this peculiarity that *Prionus coriarius* is known in Germany by the name of the *Fiddler*. Of this numerous and graceful family some are nocturnal, and frequent old woods and the trunks of ancient trees; others occur on flowers and among flowering shrubs and hedges, and are richly gilded and adorned with various colours;—while all are remarkable for their elongated bodies, their lengthened limbs, and their long and delicately formed antennæ. Several of the species are among the very largest of the coleopterous tribes. The deficiency of wood in our northern quarter of the island is a circumstance unfavourable to the frequent occurrence among us of these lovers of "forest scenery." Even of the English species commonly so called, a few of the finest are probably not original inhabitants of Britain, but have rather been accidentally imported in the larva state in foreign timber, and have afterwards, when excluded in the perfect form, contrived to wing their way, and colonize among our native woods. Their characteristic position is in countries adjoining the equator (especially in South America), and they seem to diminish both in size and number in proportion to their distance from the torrid zone. Britain in general, and more especially Scotland, are considerably to the north of the limit where these insects cease to be common; and in other respects our island presents few local peculiarities at all adapted to their increase. Yet the indefatigable Mr Stephens enumerates about one hundred indigenous species of Longicornes, including, however, certain genera, such as *Trogosita* and *Cucujus*, which Latreille and others do not admit among the long-horned tribes.

According to the system by which we are at present guided, the Longicornes are divisible in the first place into two sections.

A.

Eyes either emarginate or crescent-shaped, or elongated and narrow. Head sunk into the thorax as far as the eyes, without any neck-like restriction,—and vertical in many.

a.

In some the articulation of the palpi is in certain cases nearly in the form of a cone, or reversed triangle; in others nearly cylindrical, and truncated at the extremity. The terminal lobe of the maxillæ is straight (not curved upon the inner one at its extremity); the head generally projected or simply inclined, and when, by a rare exception (as in *Dorcacerus*), its position is vertical, its breadth then nearly equals that of the body, and the antennæ are distant at their base, and spiny. The thorax, often unequal or square, is rarely cylindrical. They are subdivisible into two lesser tribes as follows:

TRIBE 1ST, PRIONII.

Distinguished by the labrum being absent, or extremely small and indistinct; the mandibles strong, or even very

---

[2] Stephens' *Nomenclature*, col. 32.

[3] From τρωγω̃, *I gnaw*, and σιτος, *corn*.

[4] From πλατος, *breadth* or *flatness*, and σω̃μα, *body*.

[5] Latreille remarks, that in regard to the above character, the *Parandræ* perfectly resemble the Longicornes; and that hence, if we consider the little nodule as a genuine joint, both our present family and that which follows might be regarded as pertaining to the great pentamerous section.

Coleoptera Tetramera.

large among the males, and the internal lobe of the maxillæ small or imperceptible. The antennæ are inserted near the base of the mandibles, or of the emargination of the eyes, but are not surrounded by them at their origin. The thorax is most frequently trapezoidal or square, and notched or dentated on the sides.

In the genus Parandra of Lat. the antennæ are simple, almost granose, compressed, of the same size throughout, and at most as long as the thorax; and the ligula is corneous, in the form of a short segment of a circle, transverse, and without emargination. The body is depressed, and parallelopiped, with the thorax square, rounded at the posterior angles, and without any teeth or spines. These tribes are peculiar to America. In Spondylis, Fab. (*Attelabus*, Linn.) the antennæ and maxillary lobes resemble those of the preceding; but the ligula, as in all the ensuing Longicornes, is membranous. The thorax is almost globular, without margins, and unarmed with teeth or spines. The species, which are few in number, inhabit Europe, and their larvæ occur in trees of the pine tribe. In the genus Prionus[1] of authors (Plate CCXXVI. fig. 33), the antennæ are longer than the head and thorax,—serrated or pectinated in some,—simple, attenuated towards the extremity, and with elongated articulations, in others. The terminal lobe of the maxillæ is at least as long as the first two articulations of the palpi. The body is generally depressed, with the body square or trapezoidal, and either toothed or spiny, or presenting a lateral projecting angle. These insects are said to take wing only during the night or evening. When reposing they occur on trees. Some exotic species are remarkable for their great size, and their projecting mandibles. " C'est dans ce genre," observes M. Guerin, " qui sont les plus grands Coléoptères connus, puisque certaines espèces Américaines atteignent plus de six pouces de longueur."[2] The larvæ of *P. cervicornis*, which dwell in the wood of the Gossampinus, are used as articles of food. We have only four or five species of this genus in Europe, of which *P. coriarius* is the sole British species. It is one of our largest insects, measuring about fifteen lines in length. The larva lives in the decaying trunks of oaks and birch trees. It undergoes its metamorphosis under ground. *P. giganteus* is above half a foot in length. It fortunately inhabits Cayenne.

Tribe 2d, Cerambycini.

In these the labrum is very apparent, and extends across the entire width of the anterior extremity of the head; the two maxillary lobes are very distinct and projecting; the mandibles are of ordinary size, and similar, or differing but slightly, in the two sexes. The eyes are always emarginate, and surround, at least in part, the base of the antennæ, which are usually the length of, or longer than, the body. The thighs, at least the anterior four, are commonly in the form of an ovoid club, restricted to a pedicle at the base.

Latreille commences with such as have the last articulation of the palpi always obviously thicker than the preceding ones, and in the form of a triangle or reversed cone. The head is not sensibly narrowed, and prolonged anteriorly in the form of a muzzle; the thorax is not widened from before backwards, and does not present the figure of a trapezium or of a truncated cone; the elytra are neither very short and squamiform, nor abruptly narrowed a little beyond their base, and subulate at the extremity. These may be termed the *regular Cerambycini*, in contradistinction to those of a more anomalous nature, by which we shall be afterwards conducted to another tribe. They compose the genera *Cerambyx, Clytus*, and *Callidium* of Fabricius, and a portion of his *Stenocori;* and consist of the great Linnæan genus *Cerambyx*, with the addition of some *Lepturæ* of the Swedish naturalist. Certain modern entomologists have greatly augmented the number of generic groups; but Latreille regards the characters assigned for their distinction as by no means sufficiently precise. We shall here notice the principal genera, as admitted in the *Règne Animal.*

A considerable amount of species, all from South America, have the body proportionally shorter and broader than those that follow, and are remarkable for the extent of the thorax, which nearly equals half the length of the abdomen. The anterior legs at least are distant at their base. The scutellum is large in several species. The antennæ are often pectinated, serrated, or spiny. Those of this division, of which the thorax, nearly semi-orbicular and always very large, is smooth or merely chagrined, with a single tooth on either side at the posterior angles,—of which the posterior extremity of the præsternum is plane, truncated, without emargination, or emarginate, and placed upon the mesosternum,—of which the scutellum is always very large, and the legs distant at their origin—form the two following genera:—Lissonotus of Dalman (Plate CCXXVI. fig. 35), in which the antennæ are strongly compressed, serrated or semi-pectinated, and long, with the posterior extremity of the præsternum unemarginate:—Megaderus of Dejean, in which the antennæ are simple and shorter than the body, and the posterior extremity of the præsternum emarginate, and receiving the opposing end of the mesosternum. Those, again, of which the thorax is extremely unequal, tubercular, or with many dentations, and the præsternum carinated or terminated posteriorly in a point, form the following four genera,—Dorcacerus,[3] Dejean, Trachyderes, Dalman (Plate CCXXVI. fig. 37), Lophonocerus,[4] Lat. (Plate CCXXVII. fig. 1), and Ctenodes, Olivier and Klug.[5]

In other groups of species, the thorax, sometimes square or cylindrical, sometimes orbicular or nearly globular, is very much shorter than the elytra, at least in those in which it is extended in breadth, and the præsternum presents neither a carina nor pointed prolongation at its posterior extremity. The scutellum is always small, and the legs are approximate at their origin. Several, remarkable for their beautiful metallic colouring, and the agreeable odour which they exhale, exhibit rather an anomalous character in regard to the relative proportions of the palpi,—the maxillary being smaller than the labial, and even shorter than the terminal lobe of the maxillæ, which frequently projects. The body is depressed, with the anterior of the head narrow and pointed. The hinder tibiæ are often much compressed. They form the genus Callichroma[6] of Latreille (*Cerambyx*, Fab. Dejean). A species well known in England, but which we have not traced farther north than Westmoreland, and remarkable for its strong odour of roses, is the *Cal. moschata* (*Cer. moschatus* of Linn. and of the English naturalists). It measures about an inch in length. South America, and the equatorial regions of the ancient continent, furnish several species. Other Longicornes of this division, but in which the maxillary palpi are as usual at least as long as the labial, and surpass the extremity of the maxillæ, are distinguished from such as follow, by the antennæ, particularly of the males, having twelve distinct articulations instead of eleven. These parts are always long, setaceous, and not unfrequently spiny or bearded. The thorax is toothed or spiny on the sides. These are united by Latreille under the genus ACANTHOPTERA[1] (*Callichroma*, *Purpuricenus*, *Stenocorus*, Dej. Dalm.). Certain species with the thorax nearly square or cylindrical, and the elytra generally terminated by one or two spines, enter into the genus *Stenochorus* of Dalman. Others, more characteristic of the western countries of the ancient continent, form the genus *Purpuricenus* of Ziegler and Dejean. An elegant insect of a pale ashy blue, with three black spots on each elytron, and several joints of the antennæ furnished with tufts of hair, is the *Acanth. alpinus* of Lat. recently removed from the genus Callichroma. It smells strongly of musk. We took it among the Alps of Switzerland, and have since received a specimen captured in a timber-yard in Paris.

[4] From λοφος, *a tuft*, and ϰεϱας, *horn.*

[5] For the characters by which these genera are distinguished from each other, see *Règne Animal*, t. v. pp. 111–12.

[6] From ϰαλος, *beautiful*, and χϱωμα, *colour.*

The following Cerambycini have only eleven articulations to the antennæ.

In some these organs, at least in the males, are long and setaceous; the terminal article of the palpi is in the form of a reversed cone; the thorax is either square or a little dilated in the middle, or oblong and almost cylindrical; it is often rugose or tuberculated laterally. They compose the genus CERAMBYX properly so called[2] (Plate CCXXVII. fig. 2). Of these, certain species form the genus *Hamaticerus* of recent writers. Such is *C. heros* of Fab. an inhabitant of the temperate and warmer regions of Europe. It is one of the largest Coleoptera of the European continent. The larva forms deep excavations in the wood of the oak, and has been deemed by some the *Cossus* of the ancients. As it is not now the custom to eat grubs, that disputed question still remains obscure. Latreille places in this niche of the entomological system various Callichromæ (so called) of Dejean, with a smooth or but slightly unequal thorax. Most of them belong to South America. They are in general beautifully ornamented by the hand of nature, though their size is small. Some are singularly distinguished by one or more little globular tufts of hair upon the antennæ, and even the hind legs of certain species are similarly adorned. The thighs of these insects (some of which were arranged by Fabricius and Olivier among the *Saperdæ*) resemble a club-like mass, supported upon a more lengthened pedicle. The antennæ consist of long and slender articulations. In the genus GNOMA of Dejean the thorax is long and cylindrical. The palpi are almost filiform, and the inner side of the mandibles presents a tooth. The species occur in America.

In the extensive genus CALLIDIUM[3] of Olivier, the antennæ are in general scarcely longer than the body, and are rather filiform than setaceous. The thorax, always unarmed, is sometimes nearly globular or orbicular, sometimes more narrow, nearly cylindrical, and simply dilated and rounded in the centre. The palpi, always very short, are terminated by an article rather thicker and broader than the preceding ones, and in the form of a reversed triangle. These insects now form the genera CERTALLUM of Megerle and Dejean, CLITUS of Fabricius, and CALLIDIUM properly so called. Of the second and last we have several British species.

Latreille concludes our present tribe of insects with certain species, which, in regard to the palpi, the form of the head, thorax, and elytra, and their general proportions, offer some remarkable and anomalous characters. He commences with such as present a thorax analogous to that of the preceding, especially the genus *Certallum*. It is as broad as the head, and as the base of the elytra, or scarcely narrower, and is either almost cylindrical, or rounded, or nearly orbicular; in both cases wider near the middle. The terminal articulation of the palpi is sometimes attenuated near the end, and terminated in a point, sometimes thicker and truncated, and obconical. All the thighs are clubbed, and supported by an abrupt, slender, and lengthened pedicle. The elytra of the greater number are either very short, or abruptly narrowed at a little distance from their base, and then subulate.

In the genera OBRIUM of Megerle, and RHINOTRAGUS of Dalman, the elytra do not exhibit those peculiar forms; but in Necydalis, Linn. those parts are either very short and scale-like, or prolonged, as usual, as far as the extremity of the abdomen, and abruptly contracted a little beyond their origin, then greatly narrowed, and terminated in a point. They do not resemble the ÆDEMERÆ, with which they were arranged by Fabricius, except in the form of the elytra. They are divisible into two minor groups. For example, those with subulate elytra form the genus STENOPTERUS[4] of Illiger (Plate CCXXVII. fig. 5), while such as have them short and squamiform continue to bear the name of NECYDALIS (ibid. fig. 3).

Certain insects, for the most part proper to the African islands, to New Holland, New Ireland, and New Zealand, present some ambiguous characters; and, according to Latreille, ought perhaps, in a natural order, to be placed between the Lamiariæ and the Lepturetæ. In the mean time, however, he concludes with them the tribe Cerambycini. The palpi are almost filiform, with the terminal articulation nearly cylindrical, slightly attenuated towards the base. The thorax is usually smooth, or but slightly uneven, without acute tubercles, is widened posteriorly, or presents the form of a trapezium or of a truncated cone. The abdomen is almost in the form of a reversed triangle in the greater number, and the elytra are truncated at the extremity. They form four genera, viz. DISTICHOCERA, Kirby, TMESISTERNUS, Lat., TRAGOCERUS, Dejean, and LEPTOCERA of the last-named author.

b.

In other Longicornes, forming

TRIBE 3D, LAMIARIÆ,

The head is vertical and the palpi filiform, or scarcely larger at their extremity, and terminated by an article more or less ovoid, and tapering to a point. The exterior lobe of the maxillæ is a little narrowed at the extremity, and curved upon the inner division. The antennæ are most frequently setaceous and simple, and the thorax, exclusive of the lateral tubercles or spines, is nearly of an equal width throughout. Some species are apterous,—a character not exhibited by any other division of the family.

Our present tribe, in the system of Latreille, is composed of the genera *Lamia* and *Saperda* of Fabricius, of some of the *Stenocori* of that author, of the *Colobotheæ* of Dejean, and of several of his *Cerambyces*.

The genus ACROCINUS of Illiger is constituted by an insect of a very striking and extraordinary aspect, the *Cerambyx longimanus* of Linn. The genus is distinguished

Coleoptera Tetramera.

from all the Longicornes by the thorax being provided on each side with a moveable tubercle, terminated by a point or spine. The body is flattened, with the thorax transversal; the antennæ are long and slender; the anterior legs much longer than the others, especially in the males; and the elytra are truncated at the end, and terminated by two teeth, of which the exterior is the strongest. The singular species above named, of which the colours present an agreeable mixture of grey, red, and black, is known to the French colonists by the name of the *Harlequin* of Cayenne. It is a very large insect. The *Prionus accentifer* of Olivier pertains to the same genus.

All the other Lamiariæ are referable to the great genus Lamia (Plate CCXXVII. fig. 4), which, however, has been extensively subdivided in modern times. A great number of species, chiefly from South America, of which the legs are robust and the tarsi much dilated, fall under the genus Acanthocinus of Megerle and Dejean. Not more than three species are known in Europe. Of these we received *A. ædilis* (called the *Carpenter* in France), from a wood near Inverness; and Sir Thomas Dick Lauder informs us that he likewise took it in a forest of that northern county. Specimens from the neighbourhood of Kirkaldy are preserved in the collection of Sir Patrick Walker. The species is remarkable for the great extent of the antennæ, which in the males are four times the length of the body. It is characteristic of northern countries, and most of the British examples have occurred in Scotland. "Habitat frequens," says Linnæus, writing in reference to Sweden, "in linteribus et arborum truncis decorticatis, dum ex his domos struunt ruricolæ, hinc pueris nostris dicitur *Timberman* omnibus notissima species: vulgus hunc lædere religiose apud nos ducet."[1] Others of an analogous form, but of which the antennæ are garnished with hairs, compose the genus Pogonocherus[2] of the same authors. Britain produces four species, of which two occur in Scotland. Certain apterous kinds compose the genus Dorcadion[3] of Dalman. These insects are proper to Europe and the neighbouring countries of Asia. Their antennæ are generally shorter than the body, with their articulations in the form of a reversed cone, which gives them a knotted aspect. A species common on the continent of Europe (*Cer. fuliginator*, Linn.) is almost exclusively confined to calcareous soils.

Other Lamiariæ have the thorax cylindrical, and unfurnished with tubercles or spines. The body is always elongated,—in some almost linear. They compose the genus Saperda of Fab., which has been greatly subdivided. We have several British species, of which we shall here name only *S. carcharias*, an insect about an inch in length, covered with a yellowish ashy down, spotted with black, and the antennæ coloured alternately with black and grey. Its larva lives in the trunk of the poplar, and sometimes proves injurious to plantations of that tree.

B.

In this our second principal section of the Longicornes, forming

Tribe 4th, Lepturetæ,

The eyes are rounded, entire, or scarcely emarginate, and the antennæ are then inserted forwards, or at most at the anterior extremity of that feeble emargination. The head is always inclined, prolonged posteriorly behind the eyes in several, or abruptly narrowed into a neck-like form at its junction with the thorax. This last part is conical or trapezoidal, and narrowed anteriorly. The elytra become gradually narrower from the base. This tribe corresponds to the genus *Leptura* of Linnæus, with the exception of a few species which fall more naturally among the preceding tribes, and also of such as belong to the more modern genus *Donacia*. We shall here notice only a few of the genera which, as native to our own island, are the most likely to interest the British naturalist.

In the genus Rhagium (of which we have three indigenous species) (Plate CCXXVII. fig. 6), the antennæ are simple, and at most not more than half the length of the body. The terminal articulation of the palpi forms a triangular club. The head is large, almost square, with the eyes entire. The sides of the thorax are furnished with a conical or spinous tubercle. In the genus Toxotus[4] the antennæ are at least as long as the body, simple, with the first article much shorter than the head. The eyes are entire, or very slightly emarginate. The body is triangular, or forms a lengthened square, narrowed posteriorly. *T. meridianus* and *chrysogaster* are supposed to be synonymous,—in which case we have probably not more than two British species. In the genus Leptura[5] properly so called, the head is abruptly narrowed immediately behind the eyes, and the antennæ, inserted near the anterior extremity of their inner emargination, are distant at their base. The two usual eminences from which they spring are almost confounded in one plane. The thorax is almost always smooth, or without lateral tubercles. The majority of the genus occur in Europe, and Britain produces about a score. Few of them have yet occurred in Scotland, probably owing to our comparative deficiency in wood. We have met with only one species in the neighbourhood of Edinburgh, *L. ruficollis*.

FAMILY V.—EUPODA.

Some of the component parts of this family are nearly allied to the Longicornes or preceding tribes, while others so much resemble the Chrysomelæ as to have been arranged with the latter by Linnæus. The organs of manducation present the same range of affinities. Thus, among the Donaciæ, the ligula is membranous, bifid or bilobed, as among the Longicornes, and their maxillæ are very analogous to those of the latter; while among the concluding Eupoda the ligula is almost square or rounded, and analogous to that of the ensuing family, called Cyclica. At the same time the maxillary lobes are membranous, or but slightly coriaceous, whitish, or of a yellowish hue; the exterior expands towards the extremity, and has not the figure of a palpus,—a feature which allies our present family rather to that which we have left than to the one which follows. The body is more or less oblong, with the head and thorax narrower than the abdomen. The antennæ are filiform, or gradually enlarge towards the extremity, and are inserted before the eyes. These are in some entire, round, and projecting, in others slightly emarginate. The head is received posteriorly by the thorax, which is cylindrical, or in the form of a transverse square. The abdomen may be called large when compared with the other parts, and forms a lengthened square, or elongated triangle. The articulations of the tarsi, excepting the terminal one, are furnished beneath with little cushions, and the penultimate is bifid or bilobed. The posterior thighs are very large in many species,

Coleoptera Tetramera.

and it is from that character that the family derives its name. They are all winged insects, and occur on the stems and leaves of various plants, especially, so far at least as many of the European species are concerned, on the liliaceous tribes. The larvæ of the Donaciæ feed on the internal portion of the roots of aquatic plants. Those of other genera live exposed, but, after the manner of the Cassidæ, cover themselves with a case or scabbard formed of their own excrementitious matter. Latreille divides the family into two tribes.

TRIBE 1ST, SAGRIDES.

The mandibles terminate in a sharp point. The ligula is deeply emarginate or bilobed.

In some the palpi are filiform, the eyes emarginate, the posterior thighs very large and strong, and the tibiæ arcuated. We here place the genera MEGALOPUS,[1] Fab. and SAGRA properly so called (Plate CCXXVII. fig. 7). The former insects are proper to South America; the latter, although one occurs in Africa, are characteristic of China, and the great eastern islands, such as Java, the Celebes, and Ceylon. Some of the Sagræ are among the richest and most beautiful of the coleopterous tribes. There is something striking in their gigantic limbs, and their colours consist of burnished green and gold, mingled with violet and deep flame colour.

In others the palpi are enlarged at their extremity, the eyes entire, and the thighs of nearly equal dimensions. Such are the genera ORSODACNA of Lat. and PSAMMŒCUS, Boudier.[2]

TRIBE 2D, CRIOCERIDES.

The extremity of the mandibles is truncated, or presents two or three teeth. The ligula is entire, or but slightly emarginate. These insects correspond to the genus CRIOCERIS[3] of Geoffroy, which Latreille divides as follows.

In some the mandibles taper to a point, and present two or three teeth at the extremity. The palpi are filiform, the antennæ of ordinary thickness, almost granose in certain species, and chiefly composed in others of articulations in the form of a reversed cone, or perceptibly thicker towards their superior extremity.

In the genus DONACIA, Fab. (Plate CCXXVII. fig. 8), the posterior thighs are large and inflated. The antennæ are of equal size throughout, and composed of lengthened articulations. The eyes are entire, and the terminal joint of the tarsi is inclosed, for the greater part of its length, by the lobes of the preceding articulation. This interesting genus was confounded with *Leptura* by Linnæus and Degeer, and with *Stenochorus* by Geoffroy. It was established by Fabricius under its present name, from δοναξ, *a reed*, on account of the species of which it is composed being found on reeds and other aquatic plants, such as those of the genus Iris, Saggitaria, Nymphæa, &c. to which they cling with great tenacity, and on the roots of which the larvæ are supposed to feed. In the form of their bodies and antennæ they show an alliance to the Cerambycidæ, but their habits, and the structure of the cibarian organs, ally them still more closely to *Crioceris* and *Galeruca*. They are frequently bronzed or gilded in their aspect, and are covered in some cases by a fine silky down, which is supposed to prove useful to them when they fall into the water. Indeed, even in the perfect state, they are partly aquatic, and may be seen to seek repose and shelter on the under side of the leaf of a water lily, where they are necessarily submerged. According to M. A. Brongniart, the chrysalids are attached to their filaments by one edge only. M. Leon Dufour inclines to think, in consequence of anatomical investigation, that the Donaciæ ought to be formed into a particular family. His observations, as we are informed by M. Latreille, demonstrate that their hepatic vessels, in number, form, structure, and arrangement, constitute a very remarkable exception to those of the Tetramera in general, and one which even appears peculiar to the genus. These vessels only open into the chylific ventricle, while in all the other Tetramera which M. Dufour has dissected, they have two insertions, one of which is ventricular, and the other cæcal. These biliary ducts, which are only four in number, are of two different kinds, —the first are capillary, and disposed in two strongly flexed curves, and are inserted by four distinct ends into a short obround vesicle placed at the inferior and somewhat lateral extremity of the chylific ventricle,—the others are much shorter, thicker, more dilatable, thin, and tapering at both ends, with one extremity free, and separately inserted by the other into the superior and dorsal region of the ventricle. They contain a whitish pulp, which is regarded as an alimentary substance. The œsophagus is capillary, and has no dilatation in the form of crop. The chylific ventricle is beset with projecting papillæ.[4] Britain produces above twenty species of Donaciæ—a great amount, when we consider that Dejean's Catalogue contains only twenty-six in all. The genus may be regarded as characteristic of Europe, for scarcely any occur in other countries, although a few have been collected in America.

The genus CRIOCERIS properly so called, differs from the preceding in the posterior legs being scarcely, if at all, larger than the others. The antennæ become somewhat enlarged towards the extremity, are almost granose, with their articulations not much longer than broad. The eyes are elevated and emarginate, and the posterior extremity of the head forms a kind of neck behind these latter organs. These insects are of small size, their bodies narrow and elongated, and frequently ornamented with lively colours. They live on the leaves of various plants,—Liliaceæ, Asparagi, &c. and occur in gardens and meadows. When seized they produce a sharpish sound, by rubbing the superior extremity of the abdomen against the inferior extremity of the elytra. The larvæ feed on the same plants as those on which we usually find the perfect insects, and are somewhat adhesive or tenacious by means of their six scaly feet. Their bodies are soft, short, and inflated; and they protect themselves in that early state from the action of the sun and the changes of the season, by covering their backs with their own ordure. They occupy a subterranean position in the nympha state. The species are extremely numerous as the genus was originally constituted, but it has been greatly restricted in recent times. Mr Stephens gives seven as the amount of British species. Of these not above three have yet been found in Scotland. *C. asparagi* was taken near Edinburgh by Sir Patrick Walker.

In others the mandibles, instead of tapering to a point, as in the two preceding genera, are truncated. The palpi are terminated by a strongly inflated joint, truncated, with a small angular prolongation, exhibiting the appearance of another joint. The antennæ are slender, and composed of very long and almost cylindrical articulations. Such is the genus MEGASCELIS of Dejean and Lat. (Plate CCXXVII. fig. 9), peculiar to South America.

[4] *Règne Animal*, t. v. p. 136.

FAMILY VI.—CYCLICA.

In this family the first three joints of the tarsi are still spongy, or furnished beneath with pellets, the penultimate joint divided into two lobes, and the antennæ filiform, or a little larger towards the extremity; but the body is usually rounded, with the base of the thorax as broad as the elytra in such (and these are few in number) as are of an oblong form. The exterior division of the maxillæ, in its narrow and almost cylindrical form, and darker colour, presents the appearance of a palpus; the interior division is broader and destitute of a scaly tooth. The ligula is almost square or oval, entire, or slightly emarginate. It appears from the anatomical researches of M. Leon Dufour, that the alimentary canal is at least thrice the length of the body in such of the genera as have been examined; that the œsophagus is usually inflated behind the crop; and that the chylific ventricle, or stomach, is generally smooth, at least throughout a great part of its length. The biliary apparatus resembles that of the Cerambycidæ and other Longicornes, in the number and double insertion of the vessels of which it is composed;—these amount to six, two of which (except in the genus Cassida) are for the most part shorter and more slender. The larvæ have six feet; their bodies are soft, and frequently coloured. They feed, like the perfect insect, on the leaves of plants, to which they adhere by means of a viscid humour. Some enter the earth prior to their assumption of the nympha state, while others undergo that change attached to the plants on which they feed, and partly encompassed by the exuviæ of the larva. The perfect insects are of small size, but they are frequently adorned by brilliant colours and metallic splendour. They are slow and timorous in their general movements, and when attempted to be seized, they closely fold their feet and antennæ, and drop to the ground. Several species are good leapers, and the females are extremely prolific. Latreille divides this family into three tribes, according to the mode in which the antennæ are inserted.

Tribe 1st, Cassidariæ.

These have the antennæ inserted on the superior part of the head, and approximate, straight, short, filiform, and almost cylindrical, or increasing gradually towards the extremity. The mouth, situate altogether underneath, and with very short almost filiform palpi, is sometimes arched (cintrée), sometimes partially received into the cavity of the præsternum. The eyes are ovoid or round; the legs contractile and short, with the tarsi flattened,—the lobes of the penultimate articulation entirely inclosing the terminal one. The body being flat beneath, these insects, by the disposition of their tarsi, are enabled to adhere closely to the surface of vegetation, and to remain there immoveable; in other respects the body is generally orbicular or oval, and is margined all round, or overlapped, by the thorax and elytra. The head is concealed beneath the thorax, or is received into its anterior emargination. The colours are extremely varied, and are distributed in the form of spots and radiated markings, in a manner delightful to look upon. The larvæ present a less inviting aspect, and have the instinctive habit of covering themselves with their own excretions.

In the old genus Hispa,[1] of Linn. the body is oblong, with the head entirely free or exposed, and the thorax trapezoidal. The mandibles have only two or three teeth; the external maxillary lobe is shorter than the internal, and the antennæ are filiform, and borne projecting forwards. These insects now form the genera Alurnus, Fab. (Plate CCXXVII. fig. 10), and Hispa properly so called (ibid. fig. 11).

The genus Cassida,[2] Linn. and Fab. (Plate CCXXVII. fig. 12), is distinguished from the preceding by the orbicular or almost ovoid form of the body, which, however, in a small number is nearly square. The thorax, more or less semicircular, or in the form of the segment of a circle, entirely covers and conceals the head, or incloses it in its anterior emargination. The elytra, often elevated about the region of the scutellum, project over the body. The mandibles are furnished with not fewer than four teeth, and the external maxillary lobe is at least as long as the internal. The name by which the insects of this genus are distinguished was no doubt bestowed upon them on account of a strongly marked character in their structure. The edges of the thorax and elytra overlap and protect the limbs and abdomen on all sides, and the head is also nearly covered and concealed by the prothorax. Many of the species are highly ornamental, and present pleasing combinations of green and golden hues, which, however, soon disappear or diminish in intensity after the death of the insect, but may be temporarily restored by the use of hot water. These insects are herbivorous in their habits, and are fond of artichokes and thistles. The structure and habits of the larvæ are rather singular, and have been studied and described by Goedart, Roesel, Réaumur, and Degeer. They are flattish, rather broad, and beset laterally by sixteen branched spines placed horizontally on each side of the posterior and superior portion of the body. At the base of these spines may be observed seven small cylindrical truncated tunnels, each placed on a distinct segment. These are probably the stigmatic openings. The head is small, of a corneous consistence, and presents four small tubercles on each side of its superior part, and only three on its inferior. These are regarded by Degeer as genuine eyes. Six scaly feet, terminated by a brown-coloured hook, sustain the body, which is terminated by a two-branched fork, curved over the back, and usually bearing a pile of excrementitious matter, under which the larva lies in part concealed. It can elevate or depress this "stercorareous parasol" at pleasure, for the varying purposes of shade or shelter. The nymph is shorter than the larva, broad, flattened, of an oval form, and surrounded by peculiar appendages. It has an ample thorax, terminated by a circular arch, and furnished with similar points or appendages. The legs and the segments of the abdomen are perceptible. It was in the aspect of one of these nymphæ that Goedart supposed he recognised a representation of the human figure surrounded by an imperial crown. The genus Cassida presents an immense amount of species. About twenty are indigenous to Britain, several more occur on the continent of Europe, and, including exotic species, Dejean enumerates 103 as the amount (in 1821) of his then splendid, and now (1834) unrivalled collection of Coleoptera.

Tribe 2d, Chrysomelinæ.

In this tribe the antennæ are inserted in front of the eyes, near their internal extremity, and are distant at the base. None of the species are capable of leaping. They form, in the earlier works of Fabricius, the genera *Cryptocephalus* and *Chrysomela*, of which we shall here notice the principal component parts, as modified by the systematic views of recent writers.

---

[1] Perhaps from *hispidus*, shaggy.

[2] From *cassida*, a helmet.

The original genus Cryptocephalus[1] contained those Chrysomelinæ of which the head seemed plunged vertically into an arched or hood-like thorax, in such a way that the body, generally in the form of a short cylinder, or almost ovoid, and narrowed anteriorly, appears, when viewed from above, as if truncated in front, or deprived of the head. The terminal articulation of the palpi is always ovoid.

In some of these the antennæ are short, and pectinated or serrated from the fourth or fifth joint, as in the genus Clythra of Leach and Fab. of which *C. quadripunctata* (a *Chrysomela* of Linn.) may be mentioned as a well-known British species. It measures about half an inch in length, and has red elytra, with a pair of black spots on each. Its larva lives in a little coriaceous tunnel, which it drags along with it. We here place also the singular genus Chlamys[2] of Knock[3] (Plate CCXXVII. fig. 13), in which the upper surface of the body is extremely rugged and unequal. Nothing is known of the history or transformations of these insects, all of which, as far as yet observed, are natives of the new world, especially of Brazil, a region so remarkable for its entomological riches. In a state of repose they draw in their legs and antennæ close upon their body, and when not in motion are with difficulty recognised as living creatures. The species are few in number, and by no means common in collections. Mr Kirby has described a new species under the name of *Chlamys bacca*,—"Animal singulare, baccam rubicundam acinis constantem superficie rugoso simulans."[4] In the genus Lamprosoma[5] of Kirby (Plate CCXXVII. fig. 14), the body is almost globular, very smooth and convex, and the thorax extremely short, broad, gradually raised, and slightly lobate at the middle of its posterior margin.

In other groups, the antennæ, perceptibly longer than the head and thorax, are simple and filiform, or enlarged towards the extremity, or even terminated by a club,—in which case they are generally toothed like a saw, but only from the seventh joint. In several the body is oval, and narrowed in front. The last article of the antennæ is furnished with an appendage, so as to produce an appearance of twelve joints. In the genus Cryptocephalus properly so called, the body is cylindrical, and the thorax as broad as the abdomen throughout its length. The antennæ and palpi are of the same size throughout. We have above a score of species in Great Britain. In the genus Eumolpus of Kugelan the body is narrowed in front, and almost ovoid. The mandibles are of ordinary size, and the second joint of the antennæ is shorter than that which follows. Almost all of them are exotic, although a few are found in Europe, of which *E. vitis*, Fab. and certain others, are said to occur in England. According to Geoffroy, the larva of the last-named insect is extremely destructive to vineyards.

We now approach the second great genus of the present tribe, that called *Chrysomela* by Linnæus. Of its modern reconstruction we shall likewise present the reader with a general sketch. The body of these insects is usually ovoid or nearly ovular, with the head salient, projecting or merely inclined. The antennæ are simple, about half the length of the body, and most frequently granose, and insensibly enlarged. When the great Swedish naturalist established his extensive genus Chrysomela, he included within its somewhat too ample boundaries numerous groups, which the more precise observation and richer materials of later entomologists have caused to be erected into separate genera. It is thus that we owe *Erotylus*, *Colaspis*, and *Adorium* to Fabricius, *Eumolpus* to Kungelman, *Helodes* to Paykul, *Doryphora* to Illiger, and *Paropsis* to Olivier,—besides several others, to the origin of which we need not here particularly allude. Many of the species of this genus are among the most beautiful and highly adorned of all the insect tribes. Azure, and green, and gold, form their ordinary costume; and to that lustrous aspect, combined with their compact and rounded forms, they no doubt owe their title of *Chrysomela*, which in the Greek language signifies an apple of gold.[6] These insects are of small or medium size. Few of them measure more than half an inch in length, and the greater number do not equal that dimension. They are strictly herbivorous, and sometimes commit considerable ravages on agricultural and garden produce. The larvæ have in general six feet, an elongated body, beset with warts or tubercles, and terminated by a kind of nipple, which secretes a viscous fluid, used both in walking, and in order to fix the insect firmly before its conversion to the nympha state. Their transformations usually take place in the open air, in which case they are protected by the hardening of their natural envelope. Many of the species are gregarious, while others are solitary; and it is among the latter that such occur as undergo their metamorphoses under ground. We shall now enumerate the principal generic groups into which the old genus Chrysomela has been subdivided.

In some the body is always ovoid, or nearly oval, and furnished with wings; the palpi terminate in a point. These insects resemble the Eumolpi already mentioned, and differ from the ensuing Chrysomelinæ in their filiform antennæ, which are longer than half the length of the body, composed of elongated nearly cylindrical articles, of which the eleventh or terminal bears an appendage or false joint nearly half as long as the article itself. Such are Colaspis, Fab. which have no projection of the mesosternum; and Podontia, Dalman, in which that part projects in the form of a short and conical point, the end of which is received into a posterior emargination of the præsternum.[7]

In the following groups the antennæ are short, composed of articulations in the form of a reversed cone, or more or less nearly granose, and enlarged towards the extremity. The false joint or terminal appendage is very short and indistinct. In the genus Phyllocharis of Dalman there is no mesosternal projection; but in Doryphora[8] of Illiger (Plate CCXXVII. fig. 15), that part is advanced like a distinct horn. The former genus inhabits New Holland and the island of Java,—the latter is peculiar to South America. The genus Paropsis,[9] Olivier, or *Notoclea* of Marsham (ibid. fig. 16), is distinguished from all the rest of the family by the maxillary palpi, of which the terminal article is much larger than the others, and hatchet-shaped. These insects, in so far as entomological research has yet extended, seem peculiar to New Holland. The two genera next ensuing interest our native naturalists as abundant over Britain. The terminal article of their palpi is also well distinguished from the preceding, to which it is equal, if not larger, in size,—its form being more or less semi-ovoid. These insects are widely spread over most parts of the ancient continent, especially Europe. In the genus TIMARCHA of Megerle and Dejean (Plate CCXXVII. fig. 17), the species are few in number, and apterous. The elytra are joined together, the body gibbous, and the tarsi much dilated, especially in the males. They occur on the ground in woods, fields, and by the sides of highways. Their movements are slow and heavy, and a yellowish or reddish liquor frequently exudes from their articulations. Linnæus classed a well-known species of this genus (*T. tenebricosa*) as a tenebrio. It has been dissected by M. Leon Dufour, and exhibited an intestinal tube three times the length of the body. It presented no appearance of a crop; and the stomach, which was long and folded on itself, contained no sensible papillæ: some small transverse muscular bands were just discernible. The stomach is followed by a filiform intestine, then by an oblong cæcum, bordering on the rectum. As far as our own observation has extended, the species, with a few exceptions from the north of Africa, seem confined to Europe. In the genus CHRYSOMELA properly so called (Plate CCXXVII. fig. 18), the species are all provided with wings, and the terminal article of the palpi is as large or larger than the preceding ones, and in the form of a truncated ovoid, or reversed cone. The species of this delightful genus are extremely numerous, even in its now restricted state. Comte Dejean was many years ago in possession of 120 species, and we know that his collection has recently been much augmented. Even in Britain we possess about thirty species, exclusive of fourteen kinds of *Phædon* and six of *Melasoma*, genera so nearly allied in structure and economy, that some authors do not yet distinguish them from the Chrysomelæ strictly so called. We regret that within our present limits we cannot describe the species. We shall merely mention that we lately received one of the largest and most beautiful, *C. fulgida*, from the valley of Clova in Forfarshire. It was previously unknown in Scotland. Another species of very exquisite aspect, *C. cerealis*, common in France upon the broom, has of late years been taken occasionally in Wales.[1] Our own collection is indebted for it to our liberal friend and valued correspondent Mr Melly of Manchester, a skilful and accomplished entomologist, and the owner of one of the largest and probably the best conditioned of the general cabinets of Coleoptera in Britain.

[8] From δοϱυφοϱος, *a pike-bearer*, in allusion to the sternal spine.

[9] From παϱοψις, *a platter.*

Latreille terminates the tribe with such as have their maxillary palpi attenuated at the extremity, and ending in a point. These form two genera,—PHÆDON of Megerle, in which the body is ovoid or orbicular; and PRASOCURIS of Lat. (Plate CCXXVII. fig. 20).[2] Of the former, *C. fastuosa*, Linn. may be cited as a beautiful example, which occurs in great plenty at the base of Salisbury Crags and other places near Edinburgh, on the *Lamium album* or white dead-nettle,—of the latter, *P. Phellandrii* and *Beccabungæ* are well-known British species.

TRIBE 3D, GALERUCITÆ.

Characterized by the antennæ being always at least half as long as the body, of the same thickness throughout, or insensibly enlarged towards the extremity, inserted between the eyes, at a short distance from the mouth, and usually approximate at their base, and close upon a small longitudinal carina. The maxillary palpi, thickest towards the middle, are terminated by two joints of a conical form, but opposed or united by their base, the terminal one being either truncated, or obtuse, or pointed. The body is sometimes ovoid or oval, sometimes nearly hemispherical. Several, especially of the smaller kinds, have the posterior thighs very large, which gives them the power of leaping. They form the old genus *Galeruca*.

Latreille divides these insects into two principal groups, the *Isopodes*, or such as cannot leap, and the *Anisopodes*, or such as possess that faculty.

To the former belong the genera ADORIUM, Fab., of which the species are foreign; LUPERUS, Geoff., of which we possess two British species; and GALERUCA properly so called, of which our indigenous kinds are more abundant, and which is likewise extremely numerous both in Asia and America. *G. tanaceti* occurs in most parts of Britain. We took it in Sutherland. Java produces a very beautiful species, named *G. albicornis* by Dejean.

To the leaping Galerucitæ belong numerous insects, of which the posterior thighs are much enlarged. They were scattered by Fabricius through the genera *Chrysomela*, *Galeruca*, and *Crioceris*, and have been united by other naturalists under the single genus ALTICA.[3] Though of insignificant dimensions, their colours are varied and brilliant, their movements lively, and their powers of devastation considerable. They feed on the leaves of plants, and are familiarly known by the name of garden fleas. South America produces a great many species.[4] Many subdivisions have been proposed of the old genus just named. Of these, Latreille admits as established groups the genera OCTOGONOTES of Drapiez,[5] ŒDIONYCHIS, DIBOLIA, LONGITARSUS, Lat., and ALTICA properly so called. The last-named genus is the most frequent and best known in Britain. The species are of small dimensions, and occur in great numbers during the spring in humid places, and are extremely destructive both in the larva and perfect state to pot-herbs and other garden produce. The larvæ resemble those of Chrysomela and Crioceris, and some of them are remarkable for discharging an odorous and acid fluid from certain small tubercles on their backs. The nymphæ bear a likeness to those of Coccinella, and remain from fifteen to twenty days in that condition. The perfect insects are often highly adorned, and the species are extremely numerous. We shall mention merely *H. nemorum*, which is oblong-ovate, black, thickly punctured, with a longitudinal yellowish stripe on each elytron, the base of the antennæ, tibiæ, and tarsi testaceous. This species is but too abundant over all our country. "The chief dependence," say Messrs Kirby and Spence, "of our farmers for the sustenance of their cattle in the winter is

---

[1] Certain species, of a darker or more obscure complexion than the others, form the genus MELASOMA of Dillwyn, so called from *μελας*, *black*, and *σωμα*, *body*. We may mention as an example, *M. populi*, the largest of the Chrysomelidæ hitherto found in Scotland. On each of the nine intermediate dorsal segments of the larva of this species there is a pair of black, elevated, conical tubercles, of a hard substance, from all of which when touched it emits a small drop of a white milky fluid, the smell of which, according to Degeer, is almost insupportable, being inexpressibly strong and penetrating. These drops proceed at the same instant from all the eighteen scent organs, which then present a singular spectacle. The precious fluid, however, is by no means wasted when exercised, for each drop, after a momentary appearance, during which it dispenses its perfume, is withdrawn again within its receptacle, till again required. (See Degeer, t. v. p. 291; and Kirby and Spence's *Introduction to Entomology*, vol. ii. p. 246.)

Coleoptera Trimera.

another most useful root, the turnip; and they have often to lament the distress occasioned by a failure in this crop, of which these minor animals are the cause. On its first coming up, as soon as the cotyledon leaves are unfolded, a whole host of little jumping beetles, composed chiefly of *Haltica nemorum*, called by farmers the *fly* and *black jack*, attack and devour them; so that on account of their ravages the land is often obliged to be resown, and frequently with no better success. It has been calculated by an eminent agriculturist, that from this cause alone the loss sustained in the turnip crops in Devonshire in 1786 was not less than L.100,000."[1]

FAMILY VII.—CLAVIPALPI.

The insects of this family resemble the others of the same section in having the under part of the first three articulations of the tarsi furnished with brushes, and the penultimate bifid,—but they are distinguished from them by their antennæ, which are terminated by a distinct perfoliated club, and by their maxillæ armed on the inner side with a claw or corneous tooth. A few have the articles of the tarsi entire, but they still differ from other Tetramera with analogous tarsi, in their globular or ball-like form. In this family the body is usually rounded, frequently even very convex and hemispherical. The antennæ are shorter than the body, the mandibles emarginate or dentated at the extremity, and the palpi terminated by a large joint; the last joint of the maxillary palpi is very large, transverse, compressed, almost lunate. The form of the organs of manducation indicates that these insects are gnawers; and most of the European species occur on tree fungi, beneath bark, &c.

Some have the penultimate joint of the tarsi bilobed, and are not contracted like a ball. Of these, a certain number have the last article of the maxillary palpi transverse, and almost lunate or securiform. Such are the following genera. EROTYLUS,[2] Fab. (Plate CCXXVII. fig. 19), in which the intermediate articles of the antennæ are almost cylindrical, and the terminal club oblong. The corneous interior division of the maxillæ is terminated by two teeth. They are peculiar to South America.[3] TRIPLAX (*Triplax*, *Tritoma*, Fab.) differs from the preceding in the antennæ, which are almost granose, and terminate in a shorter and ovoid club. The interior division of the maxillæ is membranous, with a single small terminal tooth. The hemispherical or rounded species form the genus TRITOMA of Fab., while those of an oval or oblong shape constitute the genus TRIPLAX of that author.

The remainder of this little group have the last article of the maxillary palpi elongated, and more or less oval. Such are LANGURIA of Lat., of which the species are strangers to Europe; and PHALACRUS of Paykul (*Anisotoma*, Illiger and Fab.). The latter genus contains certain small shining hemispherical insects, frequently found on flowers. They pass the winter under moss or beneath the bark of trees, where they probably also undergo their metamorphosis. Their general colours are brown or black; their movements are rapid, and they are with difficulty seized or retained, on account of their smooth and polished surface. They differ from the last-named exotic genus, not only in their general form, but in the club of their antennæ being composed of three instead of five articulations.

In the remaining Clavipalpi all the joints of the tarsi are simple, and the body is almost globular. Such is the genus AGATHIDIUM, Illig. so named from *αγαθις*, *a clue*, probably in reference to the faculty possessed by the species of rolling themselves into a ball,—in which state they feign death in the most imperturbable manner. They occur in woods, beneath the bark of trees, and in mushrooms. We regard the genus, of which about a dozen species occur in Britain, as rather characteristic of the north of Europe. It was originally constituted by a dismemberment of Sphæridium, from which, according to the sectional system of Latreille, it stands at a great distance, having, in common with other *Tetramera*, only four articulations to all the tarsi. The same character, in this instance we fear an artificial one, also removes it widely from *Anisotoma*, *Leiodes*, and other genera with which it is, in all likelihood more naturally, conjoined by Mr Stephens and other English entomologists.[4]

TRIMERA.

Three Articulations to all the Tarsi.

This, the fourth primary section of the coleopterous order, consists of three families, of which the first two bear a strong relation to the concluding genera of the section we have just quitted. Their antennæ, almost always composed of eleven articulations,[5] terminate in a club formed by the three last joints. The club is compressed, and in the form of a reversed triangle. The first article of the tarsi is always very distinct; the penultimate is usually bilobed; and the last, presenting a knot at its base, is terminated by a pair of hooks. The elytra are not truncated, and entirely cover the abdomen. The genera of the third family, however, differ from the other two in the characters last mentioned, in which, as in several others, they make an approach to the Brachelytra, and other groups of the great pentamerous section. In their habits also they differ greatly from the rest of the trimerous families.

1ST, FUNGICOLÆ.[6]

These have the antennæ longer than the head and thorax, the body oval, with the thorax trapezoidal. The maxillary palpi are filiform, or slightly enlarged at the extremity, but not terminated by a comparatively very large and securiform article. The penultimate joint of the tarsi is always deeply bilobed. The genera are EUMORPHUS,[7] Weber (Plate CCXXVII. fig. 21), DAPSA, Ziegler, ENDOMYCHUS,[8] Web. (ibid. fig. 22), and LYCOPERDINA, Lat.[9]

2D, APHIDIPHAGI.[10]

Of the great majority of these the body is almost hemispherical, the thorax very short, transverse, nearly lunate. The antennæ terminate in a compressed obconical club, composed of the three last articles, and are shorter than the thorax. The terminal article of the maxillary palpi is very large and securiform, and the penultimate article of the tarsi is deeply bilobed. In the remainder of the family the articles of the tarsi are simple, or at least the penultimate is very slightly bifid, a character which, with certain others, distinguishes these insects from the Fungicolæ.

[10] From *aphis*, and *φαγος*, *eating.*

In the extensive and beautiful genus Coccinella, commonly called Lady-birds (Plate CCXXVII. fig. 23), the antennæ are distinctly composed of eleven articulations. The body is nearly hemispherical, the thorax very short, slightly if at all margined, and the penultimate joint of the tarsi is deeply bilobed. The head is not concealed. This genus was established by Frisch, and has been adopted by all succeeding entomologists. It serves, according to Mr Curtis, as a remarkable example of the value of structure in the combination of groups, and of the slight importance of the distribution of colour when employed to distinguish species. "As a genus, Coccinella is so natural that its appellation has never been disturbed; whereas the species composing it are so variable that many of them have been described under a great variety of names."[1]

These insects are distinguishable from the neighbouring genera of *Chrysomela* and *Erotylus* by the number of articulations of the tarsi, which never exceed three. In this character they so far coincide with *Eumorphus*, *Endomychus*, and *Dasycerus*,—but from those genera they differ in the shortness of their antennæ, the form of their bodies, and the development of the last articulation of the maxillary palpi. The general form of these beautiful, and for the most part familiarly-known insects, is hemispherical,—an aspect produced chiefly by the convex shape of the elytra. The under surface is extremely flat, and the legs are short, and, except when the insect is in motion, scarcely project beyond the lateral edges of the elytra. Leon Dufour has illustrated the anatomical structure of this genus with his accustomed accuracy. He discovered in *C. septempunctata* a salivary apparatus composed of three pair of diaphanous vessels, of extreme tenuity, more or less twisted, and extending from the hinder part of the mouth into the abdomen, where the extremities appear to float. He was, however, unable to detect the appearance of any gland or other organ of an essentially secreting nature; but when submitted to a powerful microscope, these vessels exhibited a structure entirely analogous to that of the salivary conduits observable in the dipterous and hemipterous tribes. A linear and tubular axis was perceptible through their pellucid coats, resembling that of the excrementitial secretions of the Carabidæ. The digestive canal is itself scarcely longer than the body of the insect, and is consequently nearly straight. The œsophagus seems inclosed in the head, in such a way that, to render it observable, the alimentary tube must be drawn backwards. The stomach is not preceded by any crop or gizzard. It is bilobed at its origin, where it approaches the head, and receives the œsophagus in the notch or slope produced by that bilobation. It is longer than the rest of the tube,—is very smooth and dilatable,—and was found filled sometimes with a blackish, sometimes with a yellowish pulp. Near its termination were the biliary vessels, six in number. These vessels are somewhat large in proportion to the size of the insect, and each has a distinct and isolated insertion on the stomach, like a cæcum. They have a very varicose aspect, and always appear diaphanous. The insertion of these biliary vessels indicates the limits of the stomach, and we have then a very short intestine, followed by a slightly bulged cæcum, and a rectum distinctly marked.

The larvæ of the Coccinellæ feed on Aphides, and are extremely useful in the destruction of those noxious insects which abound to the deterioration of so many valuable plants. In the perfect state many of the species pass the winter in the clefts of palings and the chinks of walls. Their eggs are usually laid in spring. These are of a yellow colour, with a disagreeable smell, and produce larvæ of an aspect very different from that of the perfect insect. In that early condition the body is much broader than deep, and is pointed towards the extremity, which bears a fleshy projection, carried by the insect on the plane of its position, and serving as a kind of supernumerary foot. The body consists of twelve rings or segments, which in some cases are garnished with spines or tubercles, in others smooth. When the larvæ have attained to their full size, they adhere by their hinder extremity to a leaf or a stone, and partly freeing themselves from a slough or skin, they assume the state of Chrysalis. In the course of a week or two, according to the species, the perfect insect makes its appearance. It is at first soft, flexible, and almost colourless, but a very short period suffices to adorn it with those gay and contrasted markings which render the Coccinellæ or "Lady-birds" among the most admired of all the smaller tribes of coleopterous insects. Some contrariety of opinion appears to exist in regard to the food and habits of these insects in the perfect state. Perhaps their instincts may vary according to circumstances, or may present a disparity in the species. We have frequently observed them preying upon Aphides; and yet Bosc, in describing the *Coccinella borealis* of America, mentions its destructive attacks upon the leaves of the melon plantations; and other species are said to be injurious to the crops of lucerne and cinqfoils. Their numbers vary greatly in different years. In 1807, as Messrs Kirby and Spence inform us, the shore at Brighton, and all the watering-places on the south coast, were literally covered with them, to the great surprise and even alarm of the inhabitants, who were ignorant that their little visitors were merely emigrants from the neighbouring hop-grounds, where in their larva state they had slain their thousands and their tens of thousands of the Aphis, which, under the name of the *Fly*, so frequently blasts the hop-grower's expectations.[2] Mr Stephens enumerates thirty British species of this genus, almost every one of which exhibits several striking varieties.[3]

In the remaining Aphidiphagi the body is very flat, in the form of a buckler, and the head is concealed beneath a nearly semicircular thorax. The antennæ do not seem to consist of more than nine articulations, and terminate in an elongated club. The articulations of the tarsi are entire. The præsternum forms anteriorly a kind of chin-cloth (*mentonnière*). Such is the genus Clypeaster, of which the species occur under stones, and beneath the bark of trees.

3d, Pselaphii.

This little family, in its short and truncated elytra, which leave the abdomen in part exposed, presents a cer-

---

[2] *Introd. to Entomology*, vol. i. p. 257; and *Entomologia Edinensis*, p. 293.

[3] The natural union of these apparently distinct kinds may have given rise to the belief that different species of Coccinellæ cohabited with each other. "On trouve quelquefois," says Latreille, "des individus très différents par leurs couleurs accouplés; mais on n'a pas suivi les résultats de ces mélanges." (*Règne Animal*, t. v. p. 162.)

Orthoptera.

tain resemblance to the brachelytrous tribes, particularly the genus Aleochara.[1] The abdomen, however, is much shorter and wider, and is very obtuse and rounded posteriorly. The antennæ terminate in a club, or are enlarged towards the extremity, and sometimes consist of only six articulations. The maxillary palpi are usually very large. All the articulations of the tarsi are entire, and the first, much shorter than the following, is scarcely perceptible on a cursory examination; the last is frequently terminated only by a single hook. These insects occur upon the ground among vegetable debris. Some are found in ants' nests.

Such as have eleven joints to the antennæ form the genus PSELAPHUS[2] of Herbst (*Staphylinus*, Linn.), which is thus subdivided by Latreille. A limited number have two hooks to the tarsi. These form the genera CHENNIUM, Lat. (Plate CCXXVII. fig. 25), and DIONIX, Dejean. The remainder have only a single hook to the tarsi. Such are PSELAPHUS proper (ibid. fig. 24) of Lat., BITHYNUS, ARCOPAGUS and BRYAXIS of Leach, and CTENISTES of Reichenbach.[3]

The last of the Pselaphii, and with these we conclude the great coleopterous order, are distinguished by this peculiarity—that the antennæ are composed of not more than six articulations, and in certain cases (genus ARTICERUS of Dalman[4]) apparently of only one. In the genus CLAVIGER[5] (Plate CCXXVII. fig. 26) six joints are quite perceptible (ibid. fig. 27). These insects do not seem to have any eyes. The maxillary palpi are very short, without distinct articulations, and furnished with two terminal hooks. The first two articulations of the tarsi are very short, the third or last very long, with a single terminal hook. These insects occur beneath stones in dry situations.[6]

ORDER II.—ORTHOPTERA.[7]

In this order the wings are likewise four in number. The elytra or upper pair are softer and more flexible than in the preceding order; they are semi-membranous, reticulated, and for the most part do not form by their junction, when closed, a straight line along the dorsal suture. The true wings are folded longitudinally, and usually after the manner of a fan, and are divided by longitudinal membranous nervures. Maxillæ terminated by a corneous piece, toothed, and protected by the galea, a portion which corresponds to the exterior division of the jaws of coleopterous insects. In this order there is also a kind of tongue or epiglottis. The metamorphosis is semi-complete.

Linnæus arranged the first genus of our present order with his Coleoptera, placing it, however, by itself at the termination of that order;—the remaining genera were grouped with his hemipterous tribes. We owe their separation to Degeer, who formed the whole into an order, under the name of *Dermaptera*.[8] They correspond to the *Ulonata* of Fabricius. The title which they now bear was imposed by Olivier.

The body of orthopterous insects is generally of an elongated form, and of a somewhat soft and fleshy consistence. It is composed as usual of head, thorax, and abdomen. We shall briefly describe the general characters of these parts. The head varies considerably in size, form, and position. It is usually large and vertical, and presents in the greater number of species two or three stemmatic eyes. The front is sometimes prolonged into a conical form, as in certain species of the genera *Truxalis* and *Mantis;* sometimes it bears a kind of fleshy appendix resembling a veil, as in the *Gryllus umbraculosus* of Spain. The true eyes occupy the sides of the head, and are generally very large, with a reticulated aspect. The antennæ do not vary so greatly in their structure as among the Coleoptera, but they are usually composed of a greater number of articulations. They are generally inserted in front of the eyes, but sometimes beneath or between them. Their articulations are not very distinct, and as to shape they are filiform, setaceous, massive, perfoliated, and sometimes ensiform, or resembling the blade of a sword.

The mouth consists of a labrum, two mandibles, a pair of maxillæ, a labium, and four palpi. The labrum is attached to the clypeus by a distinct suture; it is moveable, always external, demi-coriaceous, somewhat arched or vaulted, almost semicircular, rounded in front, and advancing on the mandibles. The mandibles are scaly, or corneous and strong, triangular, short, thick, with the exterior side arched, and the interior armed with many unequal teeth or dentations. According to the observations of Marcel de Serres, these dentations bear a close relation to the mode of nourishment; and he distinguishes them, as we do the dental system of the Mammalia, as *incisive*, *canine*, and *molar*. These last are the largest, and there is never more than one in each mandible, placed towards its base. The three sorts of teeth never exist simultaneously, and it is by their presence or absence, and by the modifications of their forms, that we may recognise the nature of the various substances by which the different tribes of Orthoptera are nourished. In the genera *Mantis* and *Empusa*, for example, which are purely carnivorous, we find only the canine teeth or *laniares*. Those species which have only incisive and molar teeth are herbivorous, while such as are omnivorous possess canine and molar teeth, but of smaller dimensions. The maxillæ resemble in a great measure those of the carnivorous Coleoptera. They are very strong, corneous, at least on their superior portion, which forms a kind of large conical tooth, provided with two or three dentations. They also bear

[6] Two additional primary sections of the order Coleoptera were formerly recognised, under the names of DIMERA and MONOMERA. These are now suppressed, for the reasons assigned at page 110 of this article.

[7] ULONATA, Fab.

[8] The order now known under the name of *Dermaptera*, and admitted as such by many modern writers, is an osculant one, connecting the *Coleoptera* and *Orthoptera*, and is composed of the genus *Forficula.* The elytra are of a coriaceous consistence, without veins, have a straight suture, and inclose wings which are folded longitudinally as well as transversely. These characters serve to connect it with the preceding order, while the form of the wings, the organs of the mouth, and the nature of the metamorphosis, exhibit its alliance to the orthopterous tribes, along with which we have consequently ranked it in the present treatise, in conformity with the views of M. Latreille, although we are aware that most English entomologists, and many foreign ones, prefer that it should be distinguished as above mentioned.

Orthoptera.

two palpi, but that which is named the internal palpus among the carnivorous Coleoptera is here transformed into a membranous inarticulate piece, sometimes cylindrical, in other instances triangular or dilated, but in all cases vaulted above, and covering the extremity of the maxillæ. It is to this particular portion, or internal maxillary palpus, that Fabricius applied the name of *galea*, or helmet, a term not very accurately translated *galette* by Olivier. The external maxillary palpi, which alone are apparent, are composed of five articulations, of which the two first are extremely short; and it is in these palpi that Olivier and Marcel de Serres suppose themselves to have discovered the organ of the sense of *smell*. The latter author observed in their interior a pair of nerves spreading themselves over the vesicular membrane which terminates their last articulation. These he names the olfactory nerves: one is furnished by the fifth pair, which springs from the inferior face of the brain, and the other by the first pair, which derives its origin from the lateral and superior face of the first ganglion of the head. Between these two nerves there is a trachea, which, before it reaches the vesicular membrane, commences to form a pneumatic pouch. This pouch is more fully developed in the interior of the palpus, and throws off numerous ramifications, which spread themselves within the cavity of the organ. It was this peculiar structure which induced Olivier and Marcel de Serres to regard these palpi as the organs of the sense of smell. We may add, however, that Latreille is by no means satisfied that they are so, and thinks that additional observation is necessary to establish this alleged fact in the physiology of insects. The labium, or ligula, of the Orthoptera, is almost membranous, elongated, slightly enlarged towards its extremity, and divided into two or four stripes or portions.

The interior of the mouth exhibits an additional piece, which some regard as a tongue; it is fleshy, longitudinal, carinated above, broader at its base, slightly restricted before its anterior extremity, rounded, immoveable, and somewhat notched at its point. The mentum is coriaceous, in form of a transverse square, rather narrow towards the summit. The labial palpi are composed of only three articulations, as among the coleopterous tribes.[1] Those of the maxillæ consist of five.

The thorax is composed, as in other cases, of a prothorax, a mesothorax, and a metathorax. The first is generally the largest, and is the only part exposed. It presents a great variety of forms, some of which are sufficiently singular. The elytra, in the greater number, are coriaceous, thin, flexible, semitransparent, and reticulated. They are occasionally almost horizontal, with a straight dorsal suture, as among the Coleoptera; but they are much more frequently more or less inclined, with their inner edges crossing each other when closed over the back. The true wings are broader than the elytra, membranous, full of reticulations, and longitudinally folded after the fashion of a fan. To this latter character, however, the somewhat anomalous genus *Forficula* (containing the earwigs) presents an exception, as in it the wings are also transversely (as well as longitudinally) folded, as among the Coleoptera. In some cases the females, and in a few instances both sexes, among the Orthoptera, are destitute of wings. In many species the elytra of the males are short or rudimentary, and in that sex also a portion of the inner margin of these parts frequently resembles talc or parchment, and exhibits large irregular nervures. It is by the rapid friction of these upon each other that the monotonous song, or *stridulation* as it is called, of many species is occasioned. In others, however, a shrill monotonous cry is produced by rubbing the posterior limbs against the edges of the elytra.

The legs of orthopterous insects are sometimes similar to each other. In other cases the anterior pair are more extensile, and are armed with spines, with which they transfix their prey,—or they are dilated, compressed, strongly toothed externally, and adapted for burrowing in the earth. The posterior legs, as among locusts and grasshoppers, are frequently much larger than the others, and fitted for powerful leaping; and both the middle and posterior pair are more widely apart from each other at their origin than among the coleopterous species. The articulations of the tarsi differ in the different tribes; but we believe that no *heteromerous* species have been yet observed. These articulations are not unfrequently furnished beneath with little membranous cushions, and the terminal articulation is always provided with a pair of hooks or claws.

The form of the abdomen varies in this order. It is divided externally into eight or nine rings, and is often terminated by projecting appendages. Many of the females are furnished with an ovipositor, composed of two portions closely applied, and frequently surrounded by a common envelope.

In relation to the anatomy of the Orthoptera, we may state, that they are all characterized by a first membranous stomach or crop, succeeded by a muscular gizzard, armed interiorly with scales or corneous teeth, according to the species. Around the pylorus, except in the *Forficulæ*, are two or more blind intestines, furnished at their base with many small biliary vessels; and numerous other vessels of a similar nature are inserted towards the middle of the intestine. The digestive system of the larvæ resembles that of the perfect insect.

M. Marcel de Serres has particularly devoted himself to the study of the internal structure of these creatures. He informs us that the Orthoptera with setaceous antennæ, such as the genera *Blatta*, *Mantis*, *Gryllo-talpa*, *Gryllus*, and *Locusta*, have only elastic or tubular tracheæ, and these of two kinds,—the one arterial, the other pulmonary. The latter alone distribute the air to all parts of the body, after having received it from the former. In the genera characterized by cylindrical or prismatic antennæ, such as *Acrydium* and *Truxalis*, the pulmonary tracheæ are replaced by vesicular ones. They are covered by cartilaginous hoops or moveable ribs, and receive air by means of tubular or elastic tracheæ, which proceed from the arterial kind. According to the same authority, the nutritive system is more or less developed, and exhibits four principal modifications. *Gryllus* and *Gryllo-talpa* in that respect excel the others. In them the crop is shaped like a bagpipe, and placed on one side, while in the rest it is on a line with the gizzard. In the latter also the hepatic vessels are inserted insulately, but in the former by means of a common deferent canal. The genera *Truxalis* and *Acrydium* (criquets), although resembling *Locusta* (*Sauterelles*) in their digestive system, differ in respect to the superior hepatic vessels, which are not furnished at their extremity with secreting vessels, and no longer form enlarged pouches, but cylindrical and elongated canals. The intestines of *Blatta* and *Mantis* present only two divisions; their nutritive system is in other respects the same. The *Forficulæ*, of which Mr Kirby and Dr Leach form a distinct order under the title of *Der-*

---

[1] This characteristic is assigned by Latreille (*Règne Animal*, t. v. p. 168) and other writers; but we have ourselves detected four articulations in the labial palpi of several genera.

maptera, do not appear to have been investigated by Marcel de Serres.[1] According to Baron Cuvier, they differ from all other Orthoptera in wanting the superior hepatic vessels.

The metamorphoses of the Orthoptera are called semicomplete, and consist chiefly in the development and increase of the elytra and wings. Both the larvæ and nymphæ feed and move about like the perfect insects, and differ chiefly by the entire want of wings in the first state, and their rudimentary condition in the second. These insects lay an immense number of eggs, of an elongated form and considerable size. They are sometimes deposited in a mass, and inclosed together within a capsule. Both young and old are extremely voracious, and frequently produce the most frightful consequences by their devastations. On the other hand, we are not aware of any recompensing advantages derivable to the human race from any species of orthopterous insects. Several eastern tribes no doubt use them as food, and seem to have done so in remote times, as indicated by the ancient name of *Acridophagi;* and the sacred writings have recorded that the food of John the Baptist in the wilderness was "locusts and wild honey." We believe that no aquatic species is contained in this order.

Mr Macleay has observed, that although there may be reason for hesitation with respect to the types of the Neuroptera, there is none in relation to the principal forms of the orthopterous order. These forms seem to have been perceived by all entomologists, and their dissimilarity has led to tribes being regarded in the light of orders. "Indeed no forms that are within the limits of an order can be more distinct from each other than those of a *Phasma, Truxalis, Locusta, Acheta, Blatta*, and *Forficula;* and we accordingly find that they have been considered as the types of so many groups by Linnæus. The affinity of *Blatta* to *Mantis* is acknowledged in the *Règne Animal.* The genus *Proscopia*, lately instituted by Professor Klug of Berlin, one of the first entomologists of the present day, proves the proximity of *Phasma* to *Truxalis;* and no entomologist is ignorant that the chain of connection from *Acridium* to *Locusta*, from *Locusta* to *Acheta*, and from this to *Blatta*, has been long since detected, and is now perfectly established. Hence some notion may be obtained of the contents of the orthopterous circle, if we reckon the above-mentioned five genera as the types of the following tribes:

1. Phasmina.
2. Acridina.
3. Locustina.
4. Gryllina.
5. Blattina.

But as this series returns into itself, and the genus *Forficula* cannot be inserted therein without disturbing its regularity, we must agree with Degeer and Mr Kirby, that it belongs to a distinct order. That this order can only be esteemed osculant between the *Orthoptera* and *Coleoptera*, the reader will perceive by referring to its place in the *Systema Naturæ.* The *Dermaptera*, for so they are termed, from its having been the name originally proposed for the *Orthoptera* by Degeer, are in fact coleopterous insects, with the metamorphosis and caudal appendages of the true *Orthoptera*."[2]

This is a much less numerous order than the preceding, in the amount at least of the ascertained species, and in Great Britain we have not above sixty different kinds.

FAMILY I.—CURSORIA.

All the feet formed for running. Wings and wing-cases almost always placed horizontally on the body. Females unprovided with a corneous ovipositor.

GENUS FORFICULA. Tarsi triarticulate. Wings folded like a fan, and refolded transversely beneath the elytra, which are extremely short, with a straight suture. The body is linear, and terminated by two moveable scaly pieces, in the form of a pair of pincers. Head exposed. Antennæ filiform, inserted before the eyes, and composed of from twelve to thirty articulations, according to the species. The ligula is forked.[3] See Plate CCXXVIII. figs. 3, 4, and 6.

The insects of this genus, known under the familiar name of *earwigs*, are frequent in moist places, beneath stones, under the loose bark of old trees, or in decayed timber. They are injurious in gardens, where they attack various kinds of fruit. They also pierce the petals of flowers, and do not refuse animal food. Our entomological cabinet, when left open for a summer night, has sometimes suffered from their depredations. They may therefore be regarded as omnivorous. Their alleged inclination to enter the *ear* is a vulgar error, not derided however even by the Swedish sage:—"Aures dormientum interdum intrans," says Linnæus, "spiritu frumenti pellenda."

We shall not here describe the species, as their general appearance must be familiar to the reader; but we shall devote a few lines to the manners of the common earwig, *F. auricularia.* The female is known to watch over her eggs with great care,—an uncommon tendency among insects. Degeer placed an earwig, with her eggs, in a box with fresh earth, early in the month of April. They had been scattered by accident about the box; but she soon collected them together, and placed herself above them, as if she were hatching. Towards the middle of May the young made their appearance. They seemed large in proportion to the eggs, and appeared as if swollen. The movement of the dorsal vessel was very perceptible through the skin. These larvæ have neither wings nor elytra. They are composed of thirteen segments, of which the first three bear the legs, and the last exhibits the germ of the pincers, which are conical and slightly divergent. The antennæ are composed of eight articulations. Degeer endeavoured to bring up the young along with their mother, and fed them with slices of apple. They were observed to cast their skins several times, and after each of these changes the antennæ gained an additional articulation. The pincers also became longer, and their points approached each other, as in the adult insect. These larvæ, however, all perished by degrees but one; and the mother also perished, and was found half devoured by her offspring, an ungrateful return for such tender solicitude. This unnatural voracity, however, probably arose from a deficiency of other food, as they are never observed to attack each other in a state of freedom. The remaining larva increased in size, and assumed the nympha state towards the end of July. The cases of the elytra and wings are flat, and closely pressed upon the back, and the pincers have assumed their usual aspect. It therefore does not greatly differ from the perfect insect.

The genus contains many species, and is widely distributed. Several sub-genera have been instituted by Dr

---

[1] They have since been examined by M. Dufour. See the note of the ensuing page.

[2] *Hor. Ent.* p. 435.

[3] For the details of internal structure of this genus, see the *Mémoire sur l'Anatomie des Labidoures*, by M. Dufour, in the 13th vol. of the *Annales des Sciences Nat.*

Orthoptera.

Leach and others; but the nature of our present article does not admit of our taking cognisance of those minor groups.

Genus Blatta. Tarsi with five articulations. Wings folded only in a longitudinal direction. Head concealed beneath the shield of the thorax. Body oval or orbicular, and depressed. Antennæ setaceous, inserted in an internal notch of the eye, and composed of a great number of articulations. Palpi long. Thorax shield-shaped. (Plate CCXXVIII. fig. 7.)

The elytra of these insects are usually as long as the body, coriaceous or semi-membranaceous; and when closed, cross each other a little at the suture. The posterior part of the body is furnished with two conical and articulated appendages. Their crop is longitudinal, their gizzard furnished interiorly with strong hooked teeth, and there are from eight to ten cæca around the pylorus.

The Blattæ, or *cockroaches*, as they are called in this country, are nocturnal insects, which seldom fly, but run with great rapidity. Some inhabit woods or the crevices of old walls, while others frequent store-rooms and dwelling-houses, where their voracious propensities produce great damage to all kinds of provisions. They likewise destroy silk and woollen stuffs, and even leather. But their ravages are chiefly confined to warm countries. The species are numerous. Olivier[1] has described thirty-seven; and many have been discovered since his time. The *Blatta orientalis* of Linn. is about an inch long, of a reddish chesnut-brown. The wings, which are shorter than the abdomen in the male, are merely rudimentary in the female, and are wanting in the larvæ of both sexes. The eggs, to the number of sixteen, are inclosed symmetrically in an oval compressed shell, which is at first white and afterwards brown. It is tolerably solid, and is toothed along its edges like a saw. The female carries it about with her for some time, and afterwards attaches it to a favourable position, by means of a gummy exudation. This species, originally imported from eastern countries, is now widely spread over Europe, and occurs as far north as Finland.

The *Blatta Americana* of Linn. is a native of South America and the Antilles; from whence it was imported into Asia and Africa, and from these to European countries, where it chiefly infests sea-port towns, preying on sugar and other colonial produce. Sonnerat has described its combats with *la Mouche verte*, a brilliant fly of the family of Ichneumonidæ. The thorax of this species is yellowish, with two spots and a border of brown. It may also be known by the great length of its antennæ.[2] Including foreign importations, we have now twelve species of the genus Blatta in Britain.

Genus Mantis,[3] Linn. Tarsi with five articulations. Wings folded longitudinally. Head not concealed. Body narrow and elongated. Palpi short, and ending in a point. Ligula quadrifid.

We may observe, that the genus *Mantis*, as originally constituted by Linnæus, contained a great variety of very singular and somewhat incongruous forms. It has since been greatly restricted, and more precisely defined, by Illiger, Latreille, Lichtenstein, and other modern writers. Thus it is distinguishable from *Empusa* of Illiger, by the antennæ, which in the latter genus are pectinated in the male sex, and by the want of the frontal prolongation of the head. From the spectre insects (*Spectrum*) with which they were likewise combined by Linnæus, the true species of Mantis may be easily discriminated by the form and relative length of the legs, which in the spectres are of uniform size. The head in Mantis is triangular, vertical, with large eyes, and three small distinct stemmata. The antennæ are simple, setaceous, inserted between the eyes, and composed of numerous articulations. The labrum is entire; the mandibles cutting or incisive; the palpi filiform, pointed, not compressed; and the ligula is composed of four parts or divisions of nearly equal length. The thorax is long, and composed almost entirely of the first segment, of which the anterior extremity is frequently dilated, and the sides rounded. The first pair of legs are held in advance and raised, the haunch being very large, and the thigh toothed and compressed; the tibia is also toothed, and terminated by a strong hook or crotchet. The other legs are slender, simple, and unarmed with teeth or spines. The elytra are horizontal, narrow, lengthened, rather thin, semitransparent, and overlap each other on their inner edges. The under or true wings are folded lengthways like a fan. The abdomen is oblong, and is terminated by two conical articulated appendages, and a compressed scaly plate, arched on the back, and composed of several short pieces received into a pair of anal valves.

Such, we conceive, are the characters of the genus Mantis properly so called. It contains a considerable number of species, all characterized by singular and eccentric forms. We do not know by what means it has happened that an insect of this genus has become, in various parts of the world, if not an object of religious worship, at least a subject of superstitious wonder and credulity. From time immemorial the Mantis, in Turkey, has been regarded as a sacred insect; and even among the apathetic Hottentots, so sparingly endowed with any thing allied to the nobler faculties, it is said to be held in still higher estimation. The *Mantis religiosa* of Europe, called *Prega-Diou* (Prie-Dieu) in the southern provinces of France, is well known as living habitually under the safe-guard of a religious veneration on the part of the peasantry, who deem it a faithful guide and guardian of children who have lost their way. It has obtained the name of *religiosa*, from the incessant movements of its fore legs, which it is continually raising into the air, and as it were clasping together. This action, however, is the result of its peculiar instinct and mode of life; for the insect, in common with the rest of the genus, is a fierce, cruel, gormandising creature, and so far from indulging, as is fondly supposed, in a state of religious abstraction, is continually seeking for what it may devour. It preys upon all the weaker insects, which it either crushes to death, or relentlessly impales alive upon the sharp spines of its own shanks. To effect this, it is perpetually moving its arms or fore-legs in the air, and closing one armed joint upon another, so that whatever insect prey approaches within its reach is immediately transfixed and devoured. In some of the French provinces it is called the *sorcerer*. Four or five different species are found in Europe, and many more occur in the warmer regions both of the old world and the new.

In the nymph or intermediate state, the Mantides are as active and voracious as the perfect insect. Following the footsteps of Rossi (author of the *Fauna Etrusca*), the writer of the present treatise has frequently watched their manœuvres on the plains of Pisa, and has more than once had occasion to regret the loss of rarer captures, in consequence of their indiscriminate voracity.

[2] For the other species, consult Degeer's *Memoires*, t. iii.; *Encyclop. Méthodique*, t. iv.; Fuessly's *Archives des Insectes*, tab. 49, 2–11; Coquebert's *Illust. Icon. Insect.* iii. 21, 1; and the *Horæ Entomologicæ* of M. Toussaint Charpentier, p. 71–78.

[3] From μαντις, *a prophet* or *soothsayer*.

But he cannot say that he ever confirmed the observation of Roesel.[1] On the back of the nymph there are four lamina or flattened cases, which contain the germs of the wings and elytra. The eggs are deposited in a lengthened mass of two rows, and protected by an envelope somewhat of the consistence of parchment. They are of a yellow colour and elongated form, and are usually attached by the female to the stalk of a plant.[2]

Such as have the front prolonged in the form of a horn, and in which the males are provided with pectinated antennæ, form the genus Empusa[3] of Illiger. Their limbs are furnished with rounded membranous appendages resembling ruffles, and in several the edges of the abdomen are festooned. (Plate CCXXVIII. fig. 1.)

Others have the anterior legs similar to the rest; the stemmatic eyes indistinct or non-existent; the first segment of the thorax shorter or not longer than the following one; the interior divisions of the ligula shorter than the lateral; the antennæ inserted before the eyes, and the head almost ovoid and advanced, with the mandibles thick and the palpi compressed. These form the genus Spectrum,[4] Stoll, which has since been divided into two,[5] both of which are truly remarkable for the singular adaptation of their form and colour to such productions of the vegetable kingdom as they most affect. The sexes often differ greatly. 1*st,* In the genus Phasma[6] of Fabricius (Plate CCXXVIII. fig. 5), the body is filiform and linear, and resembles the stem of a plant or the twig of a tree. Several are entirely apterous, or have extremely short elytra. Very large species occur in the East Indies, the Moluccas, New Holland, and South America. *P. gigas* measures nearly a foot in length. The body is green, tuberculated on the thorax; the elytra very short and likewise green; the wings are large, of a reddish-grey, reticulated, with numerous bands and spots of brown, and with a large lateral space of a coriaceous texture and greenish colour. The legs are spinous. It occurs in the East Indies. *P. Rossi*, a much smaller and apterous species, occurs in the south of France. 2*d*, In the genus Phyllium[7] of Illiger (Plate CCXXVIII. fig. 2), both the body and legs are flattened and membranous, and the first segment of the thorax is cordiform. The wings and elytra vary in their degree of development in the different species, but they frequently cover the abdomen in such a manner as to make it appear as if two leaves had fallen upon the insect. Some seem green and fresh, others brown and withered, while an intermediate kind present the red and yellow hues of autumn. This imitation, or rather representation, of the vegetable kingdom, is indeed so singular as to attract the attention and excite the astonishment of the least curious inquirer; and it is in reference to the peculiar character just mentioned that these insects are known by the name of *walking leaves.* According to some authors, the antennæ of the males are long, slender, setaceous, and composed of a great number of nearly cylindrical articulations,—while those of the females are shorter than the head, conical, granular, and composed of not more than nine articulations. It appears that this great disparity between the sexes led Latreille into an error when he formed a distinct species of *Ph. longicornis*, which is in fact the male of *Ph. siccifolia.* The latter (see the figure last referred to) is fully three inches long, very flat, and of a pale yellowish-green colour. The thorax is short and dentated on the sides, and the foliations of the thighs are likewise dentated. In the female the antennæ are very short, the elytra as long as the abdomen, and the true wings wanting. The form of the male is narrower and more lengthened, and the antennæ long and setaceous; the elytra are short and the wings long. This species, Latreille informs us, is raised by the inhabitants of the Sechelles Islands as an object of entomological commerce. The same species, and some others nearly allied, occur in India, and the great eastern islands, such as Java, the Celebes, &c.

FAMILY II.—SALTATORIA.

Posterior legs very strong, spiny, and formed for leaping.

The males of this family (which corresponds to the great genus *Gryllus* of Linn.) are musical, that is, provided with the power of producing peculiar sounds, by friction of certain parts of their structure upon others. Most of the females deposit their eggs in the earth.

Genus Gryllus. Tarsi with three articulations. Elytra and wings horizontal, the latter folded longitudinally, and forming, when closed, a slender thread-like acumination beyond the elytra. Antennæ setaceous, inserted between the eyes. Ligula with four divisions, of which the central are very small. Labrum entire, with a projecting slip in that of the female.

This genus contains the insects commonly called crickets. They inhabit both fields and dwelling-houses. The common species (*G. domesticus*, Linn.) (Plate CCXXVIII. fig. 9) is of a pale yellowish or clay colour, mingled with brown. The female bears a long ovipositor, and the male is characterized by his perpetual cry of *cree cree*, uttered most continuously during warm weather, or in the vicinity of ovens or large kitchen fires. These insects remain in their retreats during the day, and come forth in the night season to seek their prey. They feed on bread, flour, and other articles of domestic economy. Latreille says they also devour insects. The common cricket is widely distributed over Europe. In Spain it is kept by the peasantry in little cages hung by the fireside, for the sake of its song.

The field cricket (*G. campestris*) is larger than the preceding. It is of a blackish hue, with the base of the elytra yellowish. The head is large. The posterior thighs are red beneath. The female, during the month of July, lays about three hundred eggs, from which the young are excluded in fifteen days. They feed on herbs and roots, and moult or change their skins before winter. During that inclement season they lie torpid under ground, and re-appear in spring. The larvæ are apterous, the nymphæ bear the rudiments of wings and elytra, the perfect insects, which possess the power of flight, are manifested in June and July. This species inhabits Africa and all the southern countries of Europe, where the peasant children are in use to *fish* for it, by holding an ant fastened to a hair over its hole. It is foolish and fearless, and will leave its retreat if even a stalk of grass is inserted in its dwelling; hence the French expression of *sot comme un gryllon*. It occurs in England, and we heard its song near Edinburgh for the first time last summer (1833).

---

[1] "Il a conservé des Mantes en les nourissant avec des mouches ou autres insectes; quand on les mets ensemble elles se dévorent. Un mâle et une femelle de ces insectes ayant été enfermés dans un vase de verre, le premier fut saisi par la femelle, qui lui coupa la tête. Comme ces insectes sont extrêmement vivaces, le mâle vécut encore assez long-temps, et ne fut dévoré par la femelle que quand celle-ci en eut été fécondée." (Guerin.)

[2] For the species of this and the ensuing genera, see Stoll's *Representation des Spectres, des Mantes*, &c.; Lichtenstein's *Monograph*, in the sixth volume of *Linn. Trans.*; and other works.

[3] From εμπουσα, *an apparition.*

[4] From *spectrum*, a spectre or ideal form.

[5] Other minor divisions have been effected at a still more recent period, by MM. Lepelletier and Serville (in the *Encyclop. Méth.*), and by M. Latreille in his *Familles du Règne Animal.*

[6] From φασμα, *a prodigy.*

[7] From φύλλον, *a leaf.*

There are many very singular insects belonging to this genus. The *Gryllus umbraculatus* occurs in Spain and Barbary. The male is remarkable for a membranous prolongation of the head, which falls over it like a veil. India produces the *G. monstruosus*, of which the elytra and wings are spirally twisted at their extremities. A new and large species has been lately discovered in Sicily by MM. Lefevre and Bibron, and described by them under the name of *G. megacephalus*. Of this insect each particular cry, instead of being momentarily repeated, is prolonged for about half a minute, and may be heard at the distance of a mile.

We shall here briefly notice some of the allied genera. The mole-cricket now forms the genus GRYLLO-TALPA[1] (Plate CCXXVIII. fig. 8), of which the tibiæ and tarsi of the two anterior pair of legs are flattened and toothed, and so constructed as to serve for throwing back the earth while burrowing. These insects are destructive in gardens and cultivated fields, by detaching or cutting asunder the roots of plants, during the progress of their subterranean excavations. Their natural prey, however, consists of insects and worms. The female of the best known species (*G. vulgaris*, Lat.) lays from two hundred to four hundred eggs in a commodious dwelling under ground, resembling a bottle with a curved neck. The young dwell together for some time in society. The song of the male is sweet and agreeable.[2]

An insect found in the south of France by the sides of rivers, a strong leaper, of small size, and of a black colour, spotted with yellowish-white, belongs to the genus TRIDACTYLUS[3] of Olivier, characterized by having the anterior pair of legs only formed for digging. In place of the posterior tarsi, there are moveable appendages in the form of claws. The antennæ are short, of equal thickness throughout, and composed of ten articulations. The species above alluded to is the *Xya variegata* of Illiger. Charpent. *Horæ Ent.* p. 84, t. ii. fig. 2, 5.

A singular species, misnamed *Blatta acervorum* by Panzer, takes up its abode in ants' nests, and now forms a genus of our present group under the name of MYRMECOPHILA.[4] The body is oval and apterous, the posterior thighs very large. In the antennæ, and the want of stemmatic eyes, it resembles *Gryllus* properly so called.[5]

GENUS LOCUSTA. Tarsi with four articulations. Elytra and wings inclined. Antennæ very long and setaceous. Mandibles less dentated, and galea larger than in Gryllus. Females provided with an ovipositor compressed in the form of a sabre or cutlass.

These insects are herbivorous. They occur in grassy meadows, and on shrubs and trees. In flying they spring into the air, and then extend their capacious wings, but their flight is neither rapid nor long sustained. The cry of the male is sharp and continuous, and is produced by the friction of the elytra. The genus is extensive, and occurs in many countries. They are usually of a brilliant green. One of the best known in Europe (it is also an English species) is the *L. viridissima*, Lat. (Plate CCXXVIII. fig. 12). It is about two inches in length, of a fine green colour, without spots. The ovipositor is straight, and of the length of the body. Another species (*L. verrucivora*, Fab.) is likewise green, but the elytra are spotted with brown and black. The ovipositor exceeds the length of the abdomen, and is slightly arched. This latter bites pretty severely, and derives its specific name from a practice said to be followed by the Swedes, who allow it to gnaw their warts, which are alleged speedily to disappear, from the action of a black and bilious liquid which escapes from the mouth of the insect during mastication.

Several species are nearly apterous, or present merely scale-like rudiments of the organs of flight, such as the *L. ephippiger*, which now forms a genus under its specific name. Some have the antennæ bearded beneath, with the oviduct shaped like a boat, and form the genus SCAPHURA of Kirby.[6]

All the preceding genera of the leaping or saltatorial Orthoptera have this character in common, that the males effect their peculiar cry chiefly by a portion of the elytra, which is discoloured, transparent, and somewhat resembles a mirror or small tambourine. But in the following genera, the stridulation of the male is effected by the friction of the spiny legs against the sides and edges of the elytra and wings. The antennæ are sometimes filiform and cylindrical, sometimes sword-shaped, or terminated by a mass, always at least as long as the head and thorax. The ligula in the greater number has only two divisions. There are three simple eyes, the labium is notched, the mandibles much toothed, the abdomen conical and laterally compressed. The tarsi are composed of three articulations, and the female is not furnished with a prolonged ovipositor. They all leap better than the preceding genera, and have a higher and more sustained flight. They feed on vegetables, and are extremely voracious. They compose the old genus *Acrydium* of Geoffroy, which Latreille divides as follows.

*

Mouth exposed, ligula bifid, a membranous cushion between the hooks, at the end of the tarsi. GENUS PNEUMORA. Antennæ filiform, of sixteen articulations, inserted close upon the inner margin of the eye. Posterior legs shorter than the body, and less adapted for leaping. Abdomen large, vesicular, and appearing as if empty.

We know little of the manners of the insects of this genus (Plate CCXXVIII. fig. 14). They inhabit southern Africa, and feed on vegetable substances. The *P. sexguttata* has green elytra, with three silvery spots on each. It is a very beautiful insect.

GENUS PROSCOPIA, Klug. Without wings. Body long and cylindrical. Head prolonged anteriorly into a point or cone, bearing two short filiform antennæ, composed at most of seven articulations, of which the last is pointed. Posterior legs large and long, approximated to the intermediate, which are farther than usual from the anterior pair.

These singular insects are peculiar to South America, and are usually of a large size. Klug, in his monograph of the genus, has described fifteen species.[7]

Orthoptera.

GENUS TRUXALIS, Fab. Head pyramidal, bearing on its extremity, and above the eyes, two prismatic, compressed, ensiform antennæ.

We are acquainted with about a dozen species of this genus. Their distinctive characters have not yet been well expressed, and it is not improbable that several have been confounded. They are characteristic of the warmer countries of the ancient continent. The best known is the *T. nasutus* of Fab. figured by Roesel, *Insect.* ii. Gryll. iv. 1, 2. See also Drury, ii. xl. 1. It occurs in Africa and the south of Europe (Plate CCXXVIII. fig. 10).

GENUS ACRYDIUM. Head ovoid. Antennæ filiform, or terminated by a button, and inserted between the eyes, at some distance from their inner margin. Body solid, and not vesicular. Hinder legs longer than the body.

This genus contains the noted insects commonly called *locusts*, the structure and history of which we shall briefly detail. The head is largely developed, and supports two rather short antennæ, composed of twenty articulations. The true eyes are oval, projecting, and situated on the sides of the head, while the stemmatic eyes, three in number, form a triangle on its summit. The mouth is composed of a large and broad upper lip, slightly notched on its anterior margin; of strong cutting mandibles, irregularly toothed; of maxillæ terminated by three teeth, and supporting at the same time the galeæ by which they are covered, and a pair of filiform palpi, consisting of five articulations; of an inferior lip, broad, advanced, bifid at the extremity, and giving insertion to a pair of filiform palpi of four articulations. The prothorax, of the same breadth as the body, sometimes exhibits superiorly small *keels*, which are prolonged transversely on the sides in slight impressions, appearing to indicate the natural divisions of that portion of the thorax. The chest of the mesothorax and metathorax, or rather the sternum, is broad, flattened, and very dissimilar to that of *Locusta* (Sauterelles), in which it has the appearance of two triangular foliaceous plates. The elytra are coriaceous, narrow, and as long as the wings, which are large, reticulated, folded like a fan, and frequently ornamented by brilliant shades of red or blue. The legs are of unequal length,—the two anterior pair being of ordinary proportions, while the hindmost are large, and formed for leaping. Many species exhibit on each side, and near the origin of the abdomen, a large cavity, closed interiorly by a thin membranous diaphragm, of a pearly white colour. Latreille regards it as a pneumatic pouch, forming an acoustic instrument. It may no doubt be influential in regulating the sounds uttered by these insects, which, however, are certainly produced in the first place by the alternate friction of the inner face of the hind legs against the surface of the elytra.

The females, which are not provided with an exserted ovipositor, lay their eggs in some instances in the ground, in others on the stalks of plants, to which they adhere naturally by a gummy secretion, and are, moreover, enveloped and protected by a frothy matter, which hardens over them. The larvæ, the nymphæ, and the perfect insects, are all voracious, and feed on plants. The ravages of locusts are so well known to all readers of foreign travels, and accounts of their desolating inroads have been so frequently extracted, and published in numerous popular works, that a few slight notices of the subject will here suffice.

Locusts are of very common occurrence in many parts of Africa. Mr Barrow records, that in the southern districts which he visited, the surface of an area of nearly 2000 square miles might literally be said to be covered by them. The water of a wide river was scarcely visible, in consequence of the innumerable dead locusts which floated on its surface, apparently drowned in their attempts to reach the reeds which grew along its shores. Except these much wished-for reeds, they had devoured every other green thing. Their destruction on a former occasion was sudden and singular. All the full-grown insects were driven into the sea by a tempestuous wind, and were afterwards cast upon the beach, where they formed a bank three or four feet high, and extending *nearly fifty English miles.* The smell, as may be easily supposed, was most abominable, and was sensibly felt at the distance of 150 miles. In regard to the Indian locusts, a correspondent of Messrs Kirby and Spence informed these authors, that he was an eye-witness to an immense army of locusts which ravaged the Mahratta country, and was supposed to come all the way from Arabia. This column extended *five hundred miles*, and was so compact when its members were upon the wing, as to darken the sun like an eclipse, so that no shadow was cast upon the ground, and some lofty tombs, distant not more than two hundred yards from the observer, were rendered invisible. These were not the *Gryllus migratorius* of Linnæus (*A. migratorium*, Plate CCXXVIII. fig. 13), but a red species, the peculiar colour of which is said to have added additional horror to the scene;—for after having stript the trees of their foliage, they congregated around the bare and desolate branches, producing a hue like blood. When they moved again, "the sound of their wings was as the sound of chariots, and of many horses running to battle."

The migratory flight of these insects, their desolating effects upon vegetation, and consequent injury both to man and beast, have afforded a frequent subject of exercise to the pen of the poet; but by none has their injurious inroads been so magnificently portrayed as by the prophet Joel. "A day of darkness and of gloominess, a day of clouds and of thick darkness, as the morning spread upon the mountains; a great people and a strong: there hath not been ever the like, neither shall be any more after it, even to the years of many generations. A fire devoureth before them, and behind them a flame burneth: the land is as the garden of Eden before them, and behind them a desolate wilderness; yea, and nothing shall escape them. The appearance of them is as the appearance of horses; and as horsemen so shall they run. Like the noise of chariots on the tops of mountains shall they leap, like the noise of a flame of fire that devoureth the stubble, as a strong people set in battle array." "The earth shall quake before them; the heavens shall tremble: the sun and the moon shall be dark, and the stars shall withdraw their shining." "How do the beasts groan! the herds of cattle are perplexed because they have no pasture; yea, the flocks of sheep are made desolate."

Dr Southey, "the laurel-honouring laureate," as he is well called by his friend and fellow poet S. T. Coleridge, has also, in his "wild and wondrous lay" of Thalaba, sketched the progress of these destroyers.

> Onward they came, a dark continuous cloud
> Of congregated myriads numberless,
> The rushing of whose wings was as the sound
> Of a broad river headlong in its course
> Plunged from a mountain summit, or the roar
> Of a wild ocean in the autumn storm,
> Shattering its billows on a shore of rocks.

The scene of the above quotation is Arabia, where these insects are very formidable, and of different kinds. Forskal thinks that the species which chiefly infests that tented region, and which he names *Gryllus gregarius*, is distinct from the *Gryllus migratorius* of Linnæus. They come invariably from the east, which induces the Arabs to believe that they are produced by the waters of the Persian Gulf. Nejed is particularly exposed to their ravages; and no sooner have they destroyed the harvests, than they penetrate by thousands into the dwelling-houses, devouring whatever they can find, even to the leather of the water vessels. They appear in the air at a distance like clouds of smoke; and their near approach, accompanied as by a sound of falling water, stuns the inhabitants with astonishment and dread. They alight upon a field, and its verdure disappears,—the lofty palms are stript of their long shadow-casting leaves,—and pulse and all other succulent crops are voraciously devoured. Grain, however, if ripe, usually escapes, in consequence of its hardness and aridity. The Bedouins of Sinai are frequently driven to despair by the multitudes of these flying vermin, which remain for a period of a month or six weeks before they finally disappear. The time of their arrival is towards the end of the month of May, when the Pleiades are setting,—a coincidence which leads the natives to imagine that locusts entertain a dread of that beautiful constellation. Although a few are visible every year, the great flights are inflicted only every fourth or fifth season. Most of the Arabs, except those of Sinai, are in the habit of eating these insects. "In almost every town there are shops where they are sold by measure. In preparing them, the cook throws them alive into boiling water with which a good deal of salt has been mixed. After a few minutes they are taken out and dried in the sun; the head, feet, and wings are then torn off; the bodies are cleansed from the salt, and perfectly dried, after which they are put up into sacks or bags. Sometimes they are broiled in butter, and spread on the unleavened bread used at breakfast. The Jewish Arabs believe that the food of which the Israelites ate so abundantly in the desert was showers of locusts."[1] They are also used as food in several African countries, and are even exported as articles of commerce. The elytra and wings are first cut off, and then the bodies are preserved in brine. M. Miot, in his translation of Herodotus, has observed that the numerous carcasses of *winged serpents* said to have been noticed in Egypt by the early Greek historian, were in all probability masses of the dead bodies of some large species of locust. Latreille coincides in this opinion.[2]

The most noted species is that already mentioned under the name of *Acrydium migratorium* (*Gryllus migratorius*, Linn.), Plate CCXXVIII. fig. 13. It measures above two inches and a half in length. Its usual colour is green, obscurely spotted, the elytra pale brown, marked with black. The mandibles are likewise black, and the thorax is marked by a slightly elevated crest. This species is common in Poland, but occasionally extends its ravages into other European countries. It was very destructive in Provence so lately as the year 1819. It is well known in the Levant, in Barbary, and Egypt. These countries produce another species, likewise found in the south of France, the *A. lineola*, Lat. It is of a reddish-brown colour. The crest of the thorax is intersected by three impressed transverse lines; there is a conical pectoral point between the anterior legs, almost as long as the haunches; and the posterior legs are furnished with reddish spines, black at their extremity. This species is eaten in Barbary. Another kind, native to Senegal and other parts of Africa, of a yellow colour, spotted with black (it is figured by both Shaw and Denon, in their Travels), is ground when dry into powder, and used as flour. Many large exotic species are characterized by the superior portion of the thorax being greatly elevated, much compressed, and forming a sharp crest, rounded and prolonged backwards to a point. Of this kind, though of smaller dimensions, is the *A. armatum*, found in the south of Europe, and figured by Fischer.[3] Others have the elytra and wings so abbreviated, at least in one of the sexes, as to be incapable of flight. These form the generic group named PODISMA by Latreille. Such as exhibit a swelling or button-like expansion at the tips of the antennæ form the genus GOMPHOCERUS of Thunberg;—for example, the *A. sibiricum* (figured by Panzer, *Fauna Insect. Germ.* xxiii. 20), which occurs alike among the desert steppes of Siberia and the mountain passes of St Gothard.

* *

In this second section of the ACRYDIUM of Geoffroy, a part of the under portion of the head is received into a cavity of the præsternum. The ligula is quadrifid, and the tarsi are unprovided with a cushion between the claws. The articulations of the antennæ do not exceed from thirteen to fourteen. The thorax is prolonged backwards in the form of a large scutellum, sometimes exceeding the body in length. The elytra are extremely small. Such are the characters of the genus TETRIX of Latreille (Plate CCXXVIII. fig. 15), which is composed of a considerable number of small species. A good light has been thrown on their characters and classification by MM. Lepelletier and Serville, in the *Encyclopedie Méthodique*, article *Tetrix*, as well as in the more recent works of Mr Zetterstedt.[4] The genus contains the little chirping insects so frequent in this country on dry and sunny banks, and known under the familiar name of *Grasshoppers*.

ORDER III.—HEMIPTERA.[5]

The insects of this order have neither mandibles nor maxillæ properly so called. Their mouth is fitted for suction, and is composed of a tubular articulated rostrum, cylindrical or conical, curved inferiorly, or directing itself along the breast, and, when extended, presenting the appearance along its upper surface of an elongated groove or canal, in which are lodged three delicate pointed bristles, covered at their base by a ligula. These bristles form by their union a needle-like sucker, of which the tubular piece just mentioned forms the sheath, in which they are retained by means of the ligula or triangular basal portion. The inferior bristle is in fact composed of two, which unite together not far from their origin, so that the sucker itself consists of four pieces. Savigny is of opinion that the two superior bristles are analogous to the mandibles, and that the inferior represent the maxillæ[6] of the masticating orders. According to this view, which the author has illustrated with admirable assiduity and skill, the mouth of hemipterous insects is as usual composed of six principal portions, the so-called ligula representing the labrum, and the articulated sheath the labium, of the other orders.[7] According to Latreille, the languette properly so called also exists, and under a form analogous to that of the supposed labrum, but bifid at the extremity. The palpi, however, have entirely disappeared, with the exception of some slight vestiges of those parts observable in the genus *Thrips*. These representative relations between the parts of the mouth in the mandibulated and haustellated orders had in fact been sus-

Hemiptera Heteroptera.

pected by Latreille previous to their laborious demonstration by the ingenious Savigny.[1]

The elytra of a great portion of the hemipterous order are of a coriaceous texture throughout their principal extent, with their terminations membranous. They thus partake of the nature of both elytra and wings, and the order, as formerly mentioned, derives its name from that peculiarity. Among the Cicadæ and the Aphides, however, all the four wings are membranous, and frequently quite clear and transparent. In *Tettigonia*, *Membracis*, *Flatta*, &c. they are of a denser consistence; while in *Aleyrodes* they are farinaceous, and of a milky translucence. Certain kinds are apterous, as the bed-bug, some species of *Lygæus*, and the females of the cochineal insect,—but these anomalies do not remove them from the hemipterous order, to which the structure of the mouth shows them to belong.

The composition of the thorax in these insects begins to experience some modifications, which exhibit their relation to the ensuing orders. The first segment, or prothorax, in certain cases resembles in extent that of the Coleoptera; but in others it is much more minute, and becomes incorporated with the second segment, which is then manifest or exposed. The scutellum is sometimes extremely small, or altogether imperceptible; while in certain genera, such as *Scutellera* and *Membracis*, it is greatly dilated, and covers the entire upper surface of the body, concealing the elytra and wings.

The sucker, regarded as a sting, and so named by the ancient naturalists, is adapted only for the extraction of animal or vegetable matter in a fluid state. The delicate parts of which it is composed penetrate various organic substances, the nutritive juices of which are forced to flow into the interior canal by successive compressions, till they reach the œsophagus.

The antennæ of the hemipterous tribes are frequently very small, and of difficult detection. In *Psylla*, *Cimex*, *Thrips*, and others, they are very obvious; in *Cicada* they are short, simple, setaceous threads; in *Fulgora* they are still shorter and subulated; while in *Nepa*, *Ranatra*, &c. they are placed beneath the eyes, and so abbreviated as to be rendered visible only by reversing the insect.

The eyes are rather large, and between them, on the upper part of the head, in many species, there are two or three of the stemmatic kind, or ocelli, called *yeux lisses* by the French entomologists.

The nature and amount of the tarsal articulations differ according to the genera or tribes; but the greater number of hemipterous insects are characterized by three divisions of the tarsi. In some the anterior tarsi are composed of only a single piece, which is bent upon the leg in the form of a pincer; while in the aquatic genera, such as *Naucoris* and *Notonecta*, the posterior legs are oar-shaped, with the tarsi composed of two articulations.

All hemipterous insects pass as usual through three stages of mutation. But their metamorphosis is not in any case complete, and their changes consist rather in the development of the organs of flight, and the increased bulk of the body, than in any very decided or obvious transformation. Their anatomical structure exhibits a stomach with a rather solid and muscular coat, a small intestine of medium length, succeeded by a large intestine, divided into various swellings, and of a small number of biliary vessels, inserted at some distance from the pylorus.[2] The habits of the order are extremely various, as we shall show when we come to treat of the genera more in detail.

HETEROPTERA.[3]

Sucker originating from the front of the head. Elytra membranaceous at their extremity. First segment of the thorax much larger than the others. Wings horizontal or slightly inclined.

FAMILY I.—GEOCORISÆ.[4]

Antennæ exposed, longer than the head, and inserted between the eyes near their internal margin. The tarsi are composed of three articulations, of which the first is sometimes extremely short. These insects form the great genus CIMEX of Linnæus, which has now undergone many modifications. They are principally *terrestrial* insects, although some dwell upon the *surface* of waters. From several of the species a disagreeable odour emanates.

GENUS SCUTELLERA,[5] Lam. Sheath of the sucker of four distinct articulations. Labrum prolonged beyond the head, awl-shaped, and striated above. Tarsi with three articulations, the first as long or longer than the third. Antennæ filiform, of five articulations. Body usually short, oval, or rounded. Scutellum covering the abdomen. (Plate CCXXIX. fig. 1.)

The insects of this genus, formed by Lamarck from *Pentatoma* of Olivier, live on plants, of which they absorb the juices by inserting their suckers in the leaves or tender twigs. They occur in many countries, but are larger and more brilliant in equatorial than temperate regions. The *S. nobilis* of Latr. is of an elongated oval form, and of a metallic or golden blue colour, spotted with black. It is found in Asia. The *S. stokerus* is oval, green, spotted with black, and has a red abdomen. It occurs in the Antilles. Of the European species we shall mention only the *S. lineata* (*Cimex lineatus*, Linn.), which is about four lines in length, red, radiated above with black lines, and marked beneath with black spots linearly disposed. It is common in Central and Southern Europe on umbelliferous flowers.[6]

GENUS PENTATOMA,[7] Oliv. Elytra exposed. Scutellum covering only a portion of the body. Other characters as in the preceding genus.

The species of this genus, known as *wood-bugs*, and under other names, are extremely numerous. They occur in every region of the world, and under various temperatures. The species proper to the warmer countries of Africa, America, and the East Indies, attain to a considerable size, and are adorned by brilliant colours. The larvæ of these insects do not greatly differ from the perfect state, except in having neither wings nor elytra. The nymphæ possess these organs in a rudimentary state, inclosed in sheaths. Their changes of condition are accompanied by a general casting of the skin. In their various states they exist on vegetable juices, which they seem as it were to pump up by means of their suckers. Some species, however, have been seen to attack insects, even those of their own kind, and suck their softer parts. Almost all of them exhale a disagreeable and penetrating odour,

Hemiptera Heteroptera.

which adheres to whatever substance the insect touches. The eggs are deposited on the stalks of plants, regularly disposed, and made to adhere by means of a remarkably tenacious liquid. They are not unfrequently adorned by extremely agreeable colours.

A pleasant and curious narrative is given by Degeer, relating to the female of a species of this genus, the *Cimex griseus* of Linn. He found on a birch tree several of these females, each followed by a little troop of thirty or forty young ones, which accompanied their mother as chickens do a hen. The parents seemed to watch over them with the greatest solicitude. This is a singular fact in the history of insects, which for the most part are not personally regardful of the welfare of their offspring, although they seldom fail instinctively to deposit their eggs in situations the best adapted for the sustenance and preservation of the future larvæ. Several of the generic groups proposed by Fabricius, as derivable from the genus Pentatoma of Olivier, are not adopted by Latreille; while, on the other hand, several genera proposed by more recent writers have been adopted.[1]

GENUS TESSERATOMA, Pel. et Serv Antennæ with four articulations. Body very flat, membranous, with the margins much dilated, notched, and angular. Thorax prolonged posteriorly in the form of a truncated lobe. This genus was formed upon the *Edessa papillosa* and *amethystina* of Fabricius. The species are chiefly from India and the Eastern Islands (Plate CCXXIX. fig. 2). Certain species from Brazil, and we believe other countries, likewise very flat, with the margins notched and dilated, with the anterior extremity of the body forming a clypeus truncated in front, and cloven at the sides, form the genus PHLÆA of the *Encyc. Méth.* (Plate CCXXIX. fig. 3).

GENUS COREUS,[2] Fab. Antennæ with four articulations, filiform, or larger at the extremity, the last being usually shorter than the preceding. Body oval. Sheath, labrum, and tarsi similar to those parts in the genus Pentatoma, which they resemble in their habits of life.

The species of this genus have the head in general of a trigonal form, and sunk, without apparent neck, into the prothorax, which is narrow anteriorly, and broader behind. The eyes are small, but prominent. The scutellum is triangular and obvious. The elytra equal the length of the abdomen, which is depressed, with elevated edges. The legs are long and slender. These creatures are said by some authors to feed on other insects, as well as on the juices of plants. The *C. marginatus* is of an obscure brown, with two small advanced points between the antennæ. The latter have their second and third articulations fulvous. It exhales a strong smell of apples. Wolff, *Icon. Cimic.* fascic. i. p. 20, t. 3, fig. 20. The *C. hystrix* is an insect of a very bizarre appearance, found in France and elsewhere. Sparmann collected a species not very dissimilar at the Cape of Good Hope,—of a grey colour tinted in parts with reddish brown; spiny, membranous, the edges of the thorax relieved in roundish lobes. The abdomen likewise margined by numerous brown-coloured lobes. The second and third joints of the antennæ are spiny at the extremity. It was named *C. paradoxus* by Fabricius (Plate CCXXIX. fig. 4). Between the principal genus *Coreus*, Fab. and that named *Lygæus* by the same author, as now restricted, several intermediate ones occur in the system of Latreille.[3] Of these, however, we shall mention merely the genus *Neides* (Plate CCXXIX. fig. 5), distinguished by its greatly elongated and almost linear form of body, and slender limbs and antennæ.

GENUS LYGÆUS, Fab. Antennæ terminated by an elongated article, almost cylindrical, and of the same thickness as the preceding joint. The stemmatic approach the true eyes, and the membranous appendages of the elytra frequently offer only four or five nervures.

The *L. equestris* (Plate CCXXIX. fig. 6) is red, spotted with black. The thorax is black before and behind, and there are two points of the same colour on the scutellum. The elytra are traversed by a black band, and there are two small spots and a point of white upon their membranous portion. It measures about five lines in length. The abdomen has four ranges of points. The *C. apterus* (Stoll, *Cimic.* ii. xv. 103) is rather less, red, and without wings. The head, a spot on the centre of the thorax, and a large point on each elytron, are black. The extremities of the elytra are truncated, or without membranous appendages. It sometimes occurs winged. The species with the large anterior thighs have been formed into a separate genus by MM. Lepelletier and Serville. Those with angulated antennæ form the genus NEIDES of Latr. already mentioned, and the genus ALYDUS of Fab. includes such as have filiform antennæ without dilatation, and the body narrow and elongated.[4]

All the preceding genera of the Linnæan CIMICES agree in having four articulations to the sheath of the sucker, and a prolonged and striated labrum; but those which follow have only two or three apparent articulations to the sheath, and the labrum is short and without striæ. The first joint of the tarsi, and frequently the second also, are very short in the greater number.

a.

Feet inserted in the middle of the chest, and terminated by two distinct hooks, which take their origin from the central extremity of the tarsus. They are not adapted for rowing, or running on the surface of the water.

*

Rostrum straight, more or less inclosed in a sheath Eyes of ordinary dimensions. Union of the head and thorax not characterized by a narrow neck, or sudden restriction. The body is usually membranous in whole or in part, and is generally extremely flat. This group of genera composes the major part of the primitive genus ACANTHIA of Fabricius, which the author himself afterwards dismembered.

GENUS SYRTIS, Fab. Anterior feet formed of a monodactyle claw like that of the Crustacea, and serving them in like manner to seize their prey. Antennæ terminated by an oval mass or enlarged articulation, and lodged in a groove of the head and thorax.

The species of this genus feed on flies and other insects, which they seize with their fore legs, after the manner of the *Mantides*. They live in woods. The *S. crassipes* (Wolf, *Icon. Cimic.* tab. 9, fig. 82) measures about three lines and a half in length. The head and thorax are brownish red; the abdomen of a deeper hue as far as the centre,—the sides and towards the base being paler. The antennæ, under parts of the body, and feet, are reddish yellow. This is a European species. Most of the others occur in South America.

GENUS TINGIS, Fab. Body extremely flat. Antennæ with the third articulation much longer than the others, and terminated by a button.

These insects live on plants, of which they pierce the leaves and flowers, not unfrequently producing great injury to their vegetation. The species found on the peartree, and known to the continental horticulturists under the name of *tiger*, is extremely destructive. It is the *T. pyri* of Lat. and is distinguished by a white reticulated thorax, the edges raised, and inflated in the centre. The scutellum is foliaceous. The elytra are white, with two black bands. The larva of *T. clavicornis* inhabits the flowers of *Teucrium Chamædrys*, and, by piercing the petals, causes them to thicken,—thus preventing their healthy development. The puncturings of the perfect insects of this genus sometimes produce a kind of gallnut.

[3] See *Règne Animal*; *Encyc. Méthod.* t. x.; and the *Systema Ryngotorum* of Fab.

[4] *Ibid.* and *Genera Crustac. et Insect.* iii. p. 126.

GENUS ARADUS, Fab. Body formed like that of Tingis; but the antennæ are cylindrical, with the second articulation almost as long or even longer than the third.

These insects occur chiefly on the trunks and beneath the bark of trees, where they congregate during the winter. They show themselves more actively in spring. The *A. corticalis* of Wolff (*Cimic.* fasc. iii. t. ix. fig. 81) serves as a type of the genus.

GENUS CIMEX, Lat. Resembles the preceding genera in the form of the body; but the antennæ are almost setaceous, composed of four articulations, of which the first is shorter than the others, the second thick and long, the third also lengthened and more slender than the others, the last scarcely increasing in thickness at the extremity. Elytra extremely small. No true wings.

Of this genus the *C. lectularius* or bed-bug (Plate CCXXIX. fig. 7) is probably too well known in many quarters to require particular description. It deposits its eggs in the month of May. The larvæ differ from the perfect insects in wanting the elytra. This species, though mentioned by Dioscorides, is said to be not an original inhabitant of Europe. It is also believed to have been unknown in London prior to the great fire in 1666, after which calamity it was transported thither in timber from America. It is said sometimes to acquire wings, and infest young pigeons, swallows, and other birds. Latreille however is of opinion that the kind attached to the last-named birds is of a distinct species from that which troubles the lords of the creation. The best means of extirpating bugs are care and cleanliness.

* *

Rostrum exposed, arched, sometimes straight, but with the labrum projecting. The head suddenly restricted behind, so as to form a neck-like portion.

†

Eyes not remarkably large. Neck apparent.

GENUS REDUVIUS, Fab. Rostrum short, but sharp and piercing. Thorax distinctly lobed. Elytra at least as long as the abdomen. Tarsi triarticulated. Antennæ with four articulations, setaceous, and extremely slender at the extremities.[1]

The species which form this genus are predaceous, and greedily attack other insects, sucking out their juices with their sharp-pointed beaks. The *R. personatus* is about eight lines in length, and of a blackish-brown colour, without spots. It is common in France. This species, which inhabits the interior of houses, covers itself with ordure, or the sweepings of apartments, and, thus disguised, lies in wait in some obscure corner for its prey. No sooner does a fly or other feeble insect approach within a calculated distance, than it suddenly darts upon it, and sucks it to death. Sometimes it may be seen approaching its victim by slow and cautious steps, till the fly, thrown off its guard by this insidious show of peace, is instantaneously captured by one deadly spring. Its bite is so severe as to produce the immediate death of its captive; and indeed we are informed that our venerated friend Latreille having been bitten on the shoulder by a Reduvius, experienced a great swelling of the entire arm, and suffered severe pain for several hours. It is chiefly in the larva and nympha states that these insects disguise themselves in the manner just mentioned. Entomologists are acquainted with a great many species of this genus, few of which, however, are native to Europe. The rest are spread over Asia, Africa, and America.

We shall here briefly notice a few of the genera which in recent times have been formed by dismemberment of the genus Reduvius as originally constituted by Fabricius. In the genus HELOPTILUS of Lepel. et Serv. the antennæ have only three articulations, of which the last two are garnished with long hairs, disposed in two rows, and verticillated on the terminal joint. In the genus PETALOCHEIRUS of Palisot de Beauvois,[2] the two anterior legs are singularly expanded into oval plates or shield-like dilatations. These insects are of African origin. The *P. rubiginosus* is blackish-brown, with the antennæ and feet of a rust colour. The thorax is spiny on either side, and surrounded by a line of yellow. The scutellum is surmounted by a straight spine. The only other species with which we are acquainted is the *P. variegatus* of the author last named. In the genus ZELUS the form of the body is linear, and the legs very long, slender, and similar to each other. The genus PLOIARIA is characterized by the same linear body, and the like length and tenuity of limb; but the two anterior legs have the haunch elongated, and formed, as in Mantis, for the seizure of their prey.

† †

Eyes remarkably large. No apparent neck.

The insects of this subdivision run swiftly along the margin of waters, making occasionally little leaps.

GENUS LEPTOPUS, Lat. Rostrum short, arched, and spiny beneath. Antennæ setaceous. Anterior thighs large and spiny.

This genus was established by Latreille upon *L. littoralis*, a small insect about two lines in length, of an obscure ash colour, with some spots upon the elytra, and the margins of these parts whitish. Their membranous appendages are pale, with obscure nervures. The feet are pale yellow. This species was discovered in Spain by Leon Dufour; and another nearly allied to it, *L. lapidicola*, has been taken by Basoches in the department of Calvados.

GENUS ACANTHIA, Lat. Rostrum long, straight, with the labrum projecting beyond the sheath. Antennæ filiform, or slightly enlarged towards the extremity. Form of the body oval.

This genus is composed of insects belonging to the genus *Salda* of Fabricius, such as S. *striata*, *zosteræ*, *littoralis*, &c. We may regard as its type the *Lygæus saltatorius* of Fab., a species which dwells by the banks of rivers, and runs and leaps with agility. Certain species, of which the antennæ are much shorter than usual, and bent over the eyes, the body shorter and more rounded, with the scutellum rather large, form the genus PELOGONUS of Latreille. These Hemiptera approach those of the genus *Naucoris* in their nature, and seem to conduct towards them in common with the following.

b.

Four posterior feet slender and long, inserted on the sides of the chest, and distant from each other at their points of articulation. The hooks of the tarsi are very small, indistinct, and placed in a fissure of the lateral ex-

---

[1] The first joint is often united to the second, and that to the third, by means of a very small article or rotule. (*Regne Animal*, v. 202.)

[2] *Insectes recueill. en Afr. et en Amer.* fasc. i.

Hemiptera Heteroptera.

tremity of the tarsus. The feet are adapted for rowing or walking on the water. These characters are proper to the genus *Hydrometra* of Fabricius, which Latreille has divided into three, as follows.

Genus Hydrometra,[1] Lat. Antennæ setaceous. Head prolonged into a muzzle, and receiving the rostrum, of which the articulations are by no means obvious, in an inferior groove.

These insects dwell in moist places, and run upon the surface of waters. (Plate CCXXIX. fig. 8.) Their bodies are narrow, thin, linear. Their eyes are large and globular, and are placed towards the centre of the lateral parts of the muzzle, or rather muzzle-shaped head. The best known species is *H. stagnorum*, which measures about five lines in length. It is of a black or blackish-brown colour, with the feet of a redder hue. The elytra are very short, with two nervures on each. This species is common throughout Europe. The *H. fossarum* of Fab. is a native of the East Indies. We are inclined to regard it as belonging to the next genus.

Genus Gerris, Lat. Antennæ filiform. Rostrum with three articulations. Anterior feet serving the office of pincers. Second pair distant from the anterior, and as long again as the body. (Plate CCXXIX. fig. 9.)

These insects have elongated bodies, are usually of a blackish colour, and are met with on the surface of still waters, on which they advance as it were by starts. Their under surface seems covered by a peculiar coating, of a black or silvery hue, according to the position in which the insect is held, and which probably protects it from the influence of the subjacent liquid. They appear rather to row than to walk upon the surface. The species are insectivorous, and prey upon such of their own class as they can master, and especially upon any land species that have fallen accidentally into the water, and are naturally inactive in that element. These they immediately seize upon with their anterior feet. The *G. lacustris*, Lat. (*Hydrometra lacustris*, Fab.), figured on the plate above referred to, is of a blackish-brown colour, greenish above. The feet are brown. The body is terminated by a projection. This species presents some peculiarities worthy of notice. There are two varieties of it, one of which is winged, the other apterous. The former of these constitute the *punaises aquatiques très-allongées ailées* of Degeer, the latter correspond to the *punaises aquatiques très-allongées non ailées* of that author.[2] Such as make their appearance in spring, and which have without doubt passed the winter beneath the ice, or under cover of the frozen banks, are all apterous, but resemble perfect insects in every other part of their structure. Sexual intercourse takes place among them. It was this latter circumstance which induced Geoffroy to believe that they offered a remarkable exception to a general rule, and that fecundation took place in the state of nymph or larva. Degeer, in combating this opinion, maintained that these apterous insects were of a distinct kind, and perfect in their way. M. Audouin, on the other hand, is of opinion that they may be regarded as individuals of the ordinary kind, proceeding from larvæ of the preceding year, of which the development has been checked by the rigours of the winter season, and the consequent condition of torpidity. He conceives that the wings are not, in these aquatic insects, organs of the first importance, and that the influence of surrounding causes is on that account the more likely to prove effectual, and that thus they remain rudimentary, when the other parts of the body, and the generative system in particular, have attained the maximum of their development. He illustrates this point by reference to the genera *Lampyris* and *Drilus*, in which (in the females) the organs of flight of the perfect insects are scarcely if at all more developed than in the larva state, while all the interior parts of structure are fully and functionally completed. The apterous individuals, then, of *G. lacustris*, which are observed to fulfil the offices of the perfect insect, are larvæ only so far as regards the undeveloped condition of the wings.[3]

General Hardwicke has described a new species of this genus from Nepaul, under the name of *G. laticaudata*. The extremity of the abdomen is remarkable for certain processes like teeth or claws.[4]

Genus Velia. Antennæ filiform, as in Gerris; but the rostrum has only two apparent articulations, the legs are much shorter than in that genus, and are inserted at nearly equal distances from each other.

Like the preceding species, these insects live on the surface of water. Their motion, however, is more like running than swimming. The *V. currens* is blackish-brown, with the superior edges of the abdomen fulvous, spotted with black. The *V. rivulorum* is black spotted with white, the abdomen fulvous.

FAMILY II.—HYDROCORISÆ.[5]

Antennæ inserted and concealed beneath the eyes, shorter than the head, or not exceeding it in length. Tarsi composed of only two articulations. Eyes for the most part remarkably large. These Hemiptera are aquatic and carnivorous. They prick severely with their rostrum, and seize upon other insects with their anterior feet, the joints of which are bent upon themselves, so as to form a kind of pincer. Their heads appear as if sunk into or intimately united to the thorax. The rostrum is short. Their metamorphoses do not differ from those of the other Hemiptera.

Tribe 1st, Nepides.

We here place the species of the unrestricted genus Nepa of Linnæus, commonly called *water scorpions.* They have the anterior legs in the form of hooks or nippers,—composed of a thigh, sometimes large, sometimes elongated, with a groove on its under surface for the reception of the tibia, and of an extremely short tarsus, which forms as it were a hook or crotchet with the tibia. The form of the body in some is oval and much depressed, in others it is more linear. Latreille divides this tribe into the following genera.

Genus Galgulus, Lat. All the tarsi similar to each other, cylindrical, with two distinct articulations, of which the terminal is provided with two hooks. The antennæ do not appear to have more than three articulations, of which the last is the largest, and of an ovoid form.

The only species of this genus with which we are acquainted, *G. oculatus*, Lat. (*Hist. Nat. des Crust. et des Insect.* xii. 286, pl. 95, fig. 9) was placed by Fabricius in the genus *Naucoris*. It is of a dull ashy brown, with some paler spots upon the elytra. The thorax is unequal. The legs are pale brown, with deeper spots. This odd-looking insect was brought by Bosc from Carolina. Its body is short and rough. The head has little length, but is pro-

Hemiptera Heteroptera.

longed laterally into two angles which support the eyes. The prothorax is lobed posteriorly, and placed before a triangular scutellum, on each side of which are inserted the short and coriaceous elytra. The thighs of the anterior legs are swollen and dentated beneath, and the tibiæ and tarsi are applied close to them when the insect is in a state of repose. We are not aware that any thing is known of the habits of this insect, further than that it is aquatic.

Genus Naucoris,[1] Geoff. Labrum exposed, large, triangular, and covering the base of the rostrum. Antennæ simple, and consisting of four articulations. Tarsi of the anterior feet terminating in a simple point or crotchet. The middle and hinder pair of legs ciliated,—their tarsi with two articulations, terminated by a pair of hooks.

Of this genus the body is usually depressed, almost ovoid, with the head rounded anteriorly, and the eyes lengthened and depressed. The abdomen is dentated around its edges. The species are extremely active, and swim with great ease and swiftness, making use of their hinder legs as oars. They sometimes quit one pool of water for another, and they then make good use of their wings. They are extremely voracious, and destroy a great number of other insects. The larvæ and nymphs inhabit the same situations as the perfect insects, and differ from them chiefly in the absence of wings. The nymphs indeed exhibit the rudiments of these organs enclosed in a kind of case, from which they expand at the period of the completed metamorphosis. The *N. cimicoides* (*Nepa cimicoides*, Lin.) measures about six lines in length. It is of a greenish-brown, with the head and thorax paler and spotted. The eyes are blackish. The margins of the abdomen are strongly dentated. It is common throughout the fresh waters of Europe.

Genus Belostoma, Lat. Labrum sheathed. Antennæ semi-pectinated. All the tarsi with two articulations. Abdomen terminated by a pair of setæ.

The *B. grandis* (*Nepa grandis*, Fab.) may be regarded as the type of this genus. It is a very large insect, measuring nearly three inches in length. It is of a greyish colour, spotted with brown. The legs are likewise spotted. The thorax is smooth. It is common in collections of foreign insects.

Genus Nepa.[2] Labrum and setæ as in the preceding genus. Rostrum curved beneath. Anterior tarsi with only one articulation,—the middle and posterior pair with two. Antennæ appearing forked. Haunches of the anterior legs short, and the thighs much broader than the other parts.

The body in this genus is almost elliptical, and narrower and more elongated than in the preceding genera. The head is small, and partly lodged in a notch of the thorax. The setæ, which terminate the abdomen, serve, according to some authors, for the purposes of respiration in the moist and muddy places in which they dwell. The Nepæ, in their various states, inhabit the quiet waters of ponds, lakes, and marshes. They swim more leisurely than many of their congeners, and often proceed along the surface of the mud below, in search of the minute insects of which they make their prey, and which they seize with their anterior feet. Their eggs are of an oval form, and, when examined with a microscope, are seen to be crowned by an aigrette of seven small threads. Swammerdam anatomized these insects, and has given us some curious details regarding the arrangement of the eggs in the ovaries. They are so disposed that the crown-like threads of the one which is next the orifice embraces the one which follows, and so on consecutively. The generative system of the male is singular, and very complicated. The larvæ leave the eggs in midsummer. They differ from the perfect insects chiefly in wanting the wings and setæ. The nymphs acquire, as usual, rudimentary wings inclosed in sheaths, and placed on each side of the body. The perfect insect frequently quits its subaqueous abode during the dewy night, and flies about with great agility. The genus is by no means numerous in species, although these seem pretty extensively distributed over the waters of the earth.

The *N. cinerea*, Lin. (Plate CCXXIX. fig. 10), is nearly an inch in length, of an ash colour, the upper part of the abdomen red, the tail shorter than the body. We owe to M. Leon Dufour some curious and excellent observations on the anatomy of this species, and on that of *Ranatra linearis*.[3] These insects present a peculiar organ, which the French observer regards as a kind of pectoral trachea, communicating with those of the ordinary kind. It forms in *R. linearis* a pair of elegant *panaches*, or feather-like bunches, of a pearly whiteness, composed of numerous little branches, and situated in the centre of the muscular mass of the breast. In *N. cinerea* the pectoral tracheæ appear to offer the vestiges of a pulmonary organ. They consist of two oblong bodies, placed immediately below the region of the scutellum, clothed by a fine membrane, smooth, and white as satin. They are almost as long as the chest, free except at their extremities, and are filled with a substance like tow, which, when examined under the microscope, presents a homogeneous tissue, formed by vascular arbusculæ. The nervous system appears to consist of two large ganglions, the one placed beneath the œsophagus, the other in the chest betwixt the first and second pair of feet, and throwing out two remarkable cords, divided into two or three threads at their extremities. Only two biliary vessels have been yet observed.

Genus Ranatra, Fab. differs from the preceding chiefly in the linear form of the body, in the rostrum being directed forwards, and in the character of the anterior legs, of which the haunch and thigh are slender and elongated.

These insects do not excel as swimmers. They frequently leave the water in the evening, and are good flyers. They are very voracious. The *R. linearis* occurs throughout Europe. It is pale cinerous, with a yellow tinge; the abdomen reddish beneath. It measures about an inch in length, and the setaceous appendages are as long as the body. The aigrette upon the eggs of this species consists of only two setæ. The genus is by no means numerous in species, but it occurs in the East Indies and America, as well as in Europe.

Tribe 2d, Notonectides.

In this group the two anterior legs are simply curved underneath, with the thighs of the usual size, and the tarsi pointed and thickly ciliated, and resembling those of the posterior legs. Their body is ovoid or nearly cylindrical, and thickish, or less depressed than in the preceding tribe. Their posterior legs are much ciliated, and resemble oars. They are terminated by two small indistinct hooks. They swim or row with great swiftness, and frequently turn upon their backs. They correspond to

Hemiptera Heteroptera.

the genus *Notonecta* of Linnæus, which Latreille divides as follows.

Genus Corixa, Geoff. Rostrum very short, triangular, transversely striated. Anterior legs very short, with ciliated compressed tarsi, furnished with a single articulation. The other legs are elongated, and the middle pair are terminated by two very long hooks. Elytra horizontal. Scutellum not apparent. *Sigara* of Fab.

These insects are of an elongated form, the body somewhat flattened, the head large and vertical, the eyes triangular, the prothorax more developed transversely than in a longitudinal direction, but prolonged backwards to a point. They walk defectively, but swim and fly well. We think they never swim upon their backs, like the species of the following genus, but are usually seen as it were suspended by their extremity from the surface of the water, and prepare to dive instantly on the approach of danger. When seized they endeavour to pierce the skin of the captor with their sharp-pointed rostrum; and if they succeed in that effort, pain accompanied by swelling not unfrequently ensues. The genus is not extensive. We may here name, as the most frequent in the fresh waters of Europe, the *C. striata* (*Notonecta striata*, Linn.), which measures about five lines in length, brown, with numerous spots or little rays of a yellowish hue. The head, legs, and under parts of the body, are likewise of the latter colour.

We may here note, that Dr Leach assumes the *Not. minutissima* of Fabricius as the type of his genus *Sigara*. It resembles the preceding genus in many respects, but the body is rather ovoid than linear or cylindrical, and the thorax is provided with a scutellum.[1]

Genus Notonecta,[2] Geoff. Fab. Rostrum articulated and in the form of an elongated cone. All the tarsi with two articulations. The four anterior legs geniculate, with simple cylindrical tarsi. Elytra declined. Scutellum distinct.

The Notonectæ properly so called are characterized by the singular practice of swimming upon their backs, with their bodies somewhat inclined, their heads being elevated during their upward progress, and the contrary while they either rest suspended at the surface or descend towards the bottom of the pool. When these insects are in the act of swimming, they make use only of the middle and posterior pairs of legs, the anterior being applied closely to the chest; but when they walk at the bottom, or over the herbage of aquatic plants, in search of insect prey, they then bring the latter into active service, and merely trail the former after them, or alongside. The females deposit their eggs, which are long and white, on the stalks and foliage of water-plants. The young are produced in spring, and resemble the perfect insects, except in the want of wings. The nymphæ are equally active, and exhibit these organs in a rudimentary state. They are all, of whatever sex, age, or condition, predaceous in their disposition, and, in the absence of more ordinary food, will seize upon and cruelly devour their own species. We are acquainted with about a dozen of the genus, of which about a third inhabit Europe. The others occur in Asia, Africa, and America. The most familiarly known in this country is the *N. glauca* of Linn. (*Nepa notonecta*, Dejeer, *Mem. Insect.* iii. p. 382, No. 5, tab. 18, fig. 16, 17), figured on Plate CCXXIX. fig. 11. It is about half an inch in length, of a greenish black beneath, the front of the head of a pale green, the upper and anterior portion of the thorax whitish, the posterior half obscure. The elytra are of a yellowish-grey, with a tint of brown, their sides spotted. The scutellum is black. This insect varies considerably in its external aspect. Those with brown elytra, varied with reddish, may be regarded as *N. maculata* of Lat.

The *N. minutissima* of Linn. must not be confounded with the species so called by Fabricius. The former constitutes the genus *Plea* of Dr Leach, and differs from Notonecta in having the third point of the antennæ larger than the others. The articulations of the anterior tarsi are also of equal length, and the hooks of the posterior legs are large. The form of the body, and texture of the elytra, likewise present some disresemblances.

HOMOPTERA, Lat.

In this second great division of the hemipterous order, the rostrum or sucker originates from the inferior part of the head, close upon the chest, or even from between the two anterior legs. The elytra (almost always inclined) are semimembranous, and of the same consistence throughout. They are sometimes scarcely distinguishable in their texture from the inferior wings. The three component segments of the thorax are united as it were *en masse*, and the first is always shorter than the one following.

The genera of this section are quite dissimilar in their habits to those with which we have been previously engaged. They feed on the juices of plants. Many of the females are provided with a scaly sheath or ovipositor (called *oviscapte* by M. Marcel de Serres). This is usually composed of three dentated blades, lodged in a bivalvular groove. They use it as a kind of saw, with which to produce notches or other excavations in various plants, for the purpose of depositing their eggs in safety.

FAMILY I.—CICADARIÆ.

The genera composing this family present three articulations in the tarsi,—the antennæ are usually very small, conical or awl-shaped, and consist of from three to six portions, including the attenuated seta by which they are terminated. We owe to MM. Ramdhor, Marcel de Serres, Leon Dufour, and Straus, many excellent observations on the internal structure of these insects. According to Dufour, the stomach, or chylific ventricle, is of remarkable length. It commences by an oblong dilatation, either curved or straight, and decreases into an intestiniform canal, which returns upon itself, and opens near the origin of the ventricle, alongside the insertion of the hepatic vessels, and not far from the origin of the intestine. They are all provided with four biliary vessels. In the Cicadæ the ventricle has what Dufour calls "la forme d'une anse," the right portion being dilated into a large lateral, and frequently plaited pouch. Its superior extremity is united to the œsophagus by an upper ligament, and the other leads to the narrow, tubular, very long, reflexed prolongation, with the form of an intestine, which, after its circumvolutions, re-ascends to unite with the pouch near the insertion of the hepatic vessels. This truly singular disposition of the chylific ventricle, which, after several convolutions, finally disgorges into itself, by the completion of a circle traversed throughout by the alimentary fluid, is doubtless a circumstance not easily explained in a physiological point of view. It is, however, not the less a well determined fact, and one which constitutes the most characteristic feature in the anatomy of the Cicadæ and other Cicadariæ.[1] In the *Ledra aurita* of Fabricius, the inflated portion of the chylific ventricle is placed immediately after the crop; and there is but a single cluster of salivary sacks on each side, a character likewise observable in *Cercopis spumaria*, or Frog-spittle; while in Cicada there are two on each side. In *Membracis cornuta* the *anse duodenal* of Dufour is replaced by a short pouch, likewise attached to the œsophagus by a suspensory filament, a character peculiar to these insects.

1st, Stridulantes.

Antennæ composed of six articulations. Three simple eyes. This division includes the *Manniferæ* of Linnæus (Tettigonia, Fab.), and forms the

Genus Cicada of Oliv. and Lat. Head transversal. Eyes large. Prothorax broad or transversal, with a straight posterior margin; the mesothorax large, with the form of an X on its posterior edge. Elytra generally vitreous. A large scaly operculum covers a cavity on each side of the base of the abdomen in the males.

These insects differ from those that follow, not only in the structure of the antennæ and the amount of the simple or stemmatic eyes, but also in their being all destitute of the faculty of leaping. The males are musical, that is, during the heat of summer, they produce, by a peculiar structure, a loud and continuous cry or stridulation, called by courtesy a song. When we examine the lateral base of the abdomen of a male Cicada, we perceive two large scaly plates of a rounded figure, approaching that of a demi-oval cut through its smaller axis; so that each plate presents a side which is rectilinear, while the remaining portion exhibits a rounded outline. It is by the straight side that each plate is fixed without articulation, on the metathorax, of which it forms a portion. When we lift up these plates we discover a cavity on each side of the abdomen, divided into two principal chambers by a horny triangular septum. When viewed from the side of the abdomen, each cell presents anteriorly a white and plaited membrane; and lower down there is another membrane, thin, light, and transparent as glass, called *le miroir* by Réaumur. Some authors have regarded this as a kind of drum or tambour, and the seat of sound; but that organ has yet to be described. If we open the mirror from above, we perceive on each side of it another plaited membrane, moved by a very powerful muscle, composed of a great number of straight parallel fibres, and arising from the horny septum. This latter membrane is the tymbal or drum, on which the muscles act by contraction and relaxation, alternately tightening and restoring it to its original state. This is the true origin of the sound, which in fact may be produced even after the death of the insect, by jerking the muscle.[2] We may add, that M. Chabrier has perceived a stigmatic opening, not noticed by Réaumur, at the inferior junction of the mesothorax and metathorax; while Latreille has discovered on the posterior part of each tymbal a distinct hole, which, he thinks, serves for the egress of the air. Chabrier, however, is of opinion that the air makes its escape through the two stigmata placed at the base of the opercula before mentioned.[3] Further investigation will probably show that the analogues of this singular structure exist in other insects. Indeed, the principal pieces have been already recognised, though much more feebly developed, not only in the female Cicadæ, but also in certain species of the orthopterous genera *Acrydium* and *Truxalis*. In the opinion of Audouin, the plates or shutters (*volets*) are merely large prolongations of the *epimera* of the metathorax.[4]

The Cicadæ dwell on shrubs and trees, of which they suck the juices. The females, which are provided with ovipositors, lay their eggs in holes, which they form in the small branches or twigs of trees. The parts thus attacked are easily recognised by little irregularities, formed by a portion of the wood which has been raised. These elevations are placed in a row, one after the other, upon the same side of the branch. The different holes have a diameter nearly equal. Their depth is from three to four lines. They commence in an oblique direction; but as soon as they reach the pith, they become nearly parallel with the twig itself. The ovipositor does not pierce beyond the pith; and the number of eggs placed in each hole varies from four to ten. They are white, oblong, and pointed at both ends. The larvæ are white, and furnished with six feet. They soon quit their sylvan nurseries, and make their way under ground, where they gnaw the roots of plants. Their anterior legs are short, with strong dentated thighs, and are well adapted for digging. They increase rapidly in size, and are ere long transformed into nymphs. These are of a dingy-white colour, and are chiefly remarkable for their very short and inflated fore legs, which are dentated, and serve them to penetrate the earth. After living for about a year in this state, they leave the ground during the prevalence of warm weather, and, climbing up the stems of trees, their skin first hardens, and then bursts all along the centre of the dorsal line. The perfect insect then escapes from its exuviæ. It is at first very soft, and of a greenish colour; but it soon attains a firmer consistence, and various external markings make their appearance, according to the characteristic aspect of the different kinds.

These insects were well known to ancient writers, and their so-called song has been celebrated by poets from the highest antiquity. To ourselves it appeared monotonous and fatiguing, although heard not seldom among the leafy groves which shadow the fair white walls of the "Etrurian Athens." The Cicada is the insect so frequently and fondly commemorated by the Greek poets under the name of τεττιξ,—which our translators have generally though erroneously construed *grasshopper*. Linnæus, with his accustomed propriety, applied the term *Gryllus* to the locust and grasshopper tribes, and that of Cicada to the "beloved of the Athenians." The name of tree grasshopper, however, which is sometimes used, applies with sufficient accuracy to the latter, and indicates one of its characteristic habits, that of usually perching upon trees. The true grasshoppers are ground insects. The Cicadæ are scarcely known in Britain, although the species attached to ash-trees (*C. orni*) is recorded as an English insect, in common with *C. hæmatodes*. They abound in Italy and other southern parts of Europe. The Italians call them *Cicale* and the French *Cigales*, both words being no doubt derived from the Latin. They are frequently mentioned by the modern Italian poets; and Lord Byron somewhere alludes to the "shrill Cigala, people of the pines," thus recognising their *arboreous* disposition. Although held in the highest estimation as *children of the soil* by the Athenians, who used to wear golden images of them in their hair, there is no doubt that they were also regarded by the Greek nations under a less intellectual aspect. Aristotle mentions that they were used as food, and that they were particularly esteemed just before the conclusion of the nympha state. The insect which he mentions under the name of *Tettigometra*, or mother of the Cicadæ, is in fact merely that intermediate condition of nymph, prior to the development of the organs of flight. In that state, as well as when under the form of larva, it lives upon the ground, or even beneath it, feeding on herbage and the roots of plants; but when about to undergo its final metamorphosis, it climbs a tree, its outer garment bursts asunder and is thrown off as exuviæ, the wings expand their folds "voluminous and vast," and we have then the perfect insect or tree grasshopper, the Cicada of the Latins, and Tettix of the Greeks, so beautifully addressed by Anacreon:—

[3] *Essai sur le Vol des Insectes.*

[4] *Dict. Class. d'Hist. Nat.* iv. 125.

> We deem thee blest, thou grasshopper, as on the highest trees,
> Having sipp'd a little dew, thou sitt'st, like a monarch, at thine ease;
> For every thing before thee, whate'er the fields produce,
> And the fruits of every season, are intended for thy use.
> Thou art the friend of husbandmen, since harmless are thy ways;
> By mortals held in reverence, sweet seer of summer days.
> The muses love thee dearly, to Phœbus art thou dear,
> Who with that voice hath gifted thee, so musical and clear.
> Song-skilled, earth-born, song-loving one, old age to thee's no load;
> Fleshless, bloodless, passionless, thou almost art a god.

A great variety of opinion seems to prevail regarding the musical accomplishments of these celebrated insects. Virgil accused the Italian Cicadæ of bursting the very shrubs with their noise—"Et cantu querulæ rumpent arbusta Cicadæ;" and Dr Shaw in his Travels calls it, alluding to its shrilly cry, "the most troublesome and impertinent of insects." Kirby and Spence tell us that in some countries it is execrated for its deafening din. Yet some one who desired to compliment Plato, asserted that his voice was as sweet as a grasshopper's; and we may all remember the story of the rival musicians (Eunomus and Ariston), one of whom gained the victory in consequence of a Cicada settling on his harp, and supplying the place of a broken string. Even at this day the song of the *Tettigonia Tibicen* of Surinam is supposed so greatly to resemble the sound of a musical instrument, that the insect itself is called the *Harper*. The following is Mr Elton's translation of Meleager's invocation.

> O shrill-voiced insect! that with dew drops sweet,
> Inebriate, dost in desert woodlands sing;
> Perched in the spray-top with indented feet,
> Thy dusky body's echoings harp-like ring:
> Come, dear Cicada! chirp to all the grove,
> The Nymphs and Pan, a new responsive strain;
> That I, in noonday sleep, may steal from love,
> Reclined beneath the dark o'erspreading plane.

We shall here conclude our general sketch of these insects by observing that the substance used in medicine, and known by the name of *manna*, is an exudation from certain species of ash (*Fraxinus rotundifolia et ornus*) which flourish in the south of Europe. It has been observed to be frequently produced by the puncturing of the Cicadæ, which feed on the juices of those saccharine trees. The largest insect of the genus in Europe is *C. plebeia* of Linn. Its cry is very strong and shrill; and as it is well known in Italy, there can be no doubt of its being the species mentioned by Virgil. If identical with the Athenian Cicada, its voice does certainly by no means correspond in musical intonation to what might be inferred from its recorded character as a lyrist among the ancient Greeks. The pleasure produced may however depend upon association; for, as Cowper says,

> Sounds inharmonious in themselves, and harsh,
> *Yet heard in scenes where peace for ever reigns,*
> *And only there*, please highly for their sake.

It is said that the males alone are musical, which may perhaps be one reason for their continued cheerfulness; for, as the Rhodian Xenarchus has it,

> Happy the Cicadas' lives,
> Since they all have voiceless wives.

The amount of species in the genus Cicada is considerable. They are spread over almost all the regions of the earth, especially in the warmer latitudes.[1] The greater number are foreign to Europe. Our bounds will not admit of more than a brief notice of a very limited number of species. The *Cicada Orni* is a European insect, common in France and Italy. It is about an inch long, yellowish, paler beneath, but mixed with black on the upper portions. The margins of the abdominal segments are reddish. There are two rows of blackish spots on the upper wings, those next the inner margin being the smallest. Its voice is hoarse, and does not extend so far as that of several other species. This is the kind which, by wounding the tree from which it derives its specific name (a species of wild ash), causes a peculiar and honey-like fluid to flow from it. It afterwards dries and hardens, and in that state is used medicinally under the name of manna. The *C. plebeia*, Lin. (*Tettigonia fraxini*, Fab.), figured on Plate CCXXIX. fig. 13, is the largest species found in France. It is black, with some spots on the first segment of the thorax, its posterior margin, the raised and arched portions of the scutellum, and several veins on the elytra, reddish: Its cry is strong and shrill. The *C. hæmatodes* is black, with the front of the thorax and legs spotted. The edges of the abdominal segments, and the reticulations of the elytra, are red. This species occurs in the south of France, but is rare in the vicinity of Paris. Its voice is weaker than that of the preceding species. Olivier has described sixty-six species in all.[2] We are indebted to Stoll for a monograph of the Cicadæ, already referred to in a subjoined note.

2D, MUTÆ.

Antennæ with only three distinct articulations. Two ocelli or simple eyes. Legs, in general, adapted for leaping. Neither sex provided with organs of sound. The elytra are frequently coriaceous and opake, and the females of many species are observed to envelope their eggs in a white and cottony substance.

A. *Fulgorellæ.*

Antennæ inserted immediately beneath the eyes, and the front frequently prolonged into a muzzle, of variable figure according to the species.

GENUS FULGORA.[3] Front of the head prolonged or expanded into a muzzle. No appendages beneath the antennæ. Thorax of two apparent segments,—the posterior margin of the first straight, of the second triangular.

These insects are remarkable for the varied and beautiful markings of their elytra and wings, and for the singular form of their expanded muzzles, from which a luminous or phosphoric emanation proceeds during the night. Hence several of the species are known (in common with *Elater*, *Lampyris*, and other coleopterous kinds) under the name of fire-flies. The greater number of the species are exotic, and inhabit the sultry regions of Cayenne, Guadaloupe, Senegal, the East Indies, and China. They

Hemiptera Homoptera.

dwell on trees, but their special manners are but slightly known. We shall here indicate a few of the more noted species.

F. laternaria, Linn. is a large and remarkable insect from South America, drawn and described in most illustrated works on entomology. Its muzzle is nearly straight as to its direction from the head, but it is vesicular and inflated, or swollen out and rounded, at the sides and extremity. The ends of the under wings are pleasantly varied with black and yellow, in the form of an expanded spot, resembling the eye of a peacock's feather. Madame Merian informs us, that from the head or front of this species a light is seen to shine during the darker hours, so clear and brilliant that it is easy to read by its rays. She adds, that during the day it is transparent as a bladder, and radiated with red and green. The indefatigable and accurate Réaumur, desirous to ascertain by anatomical investigation the proximate cause of this curious phenomenon, opened one of these vesicular expansions, but he found it empty, except of air, and containing no organic structure. We must bear in mind, however, that the individual examined was in a state of desiccation. The species is common at Guadaloupe and Cayenne, where it is known by the name of fire-fly. It flies well, and hovers habitually about the summits of the tallest trees. Its luminous faculty has been sometimes called in question, especially by M. Richard, who captured many at Cayenne, but never saw them shine. Yet the testimony of Madame Merian, and the general application to the species of the name of *mouche à feu*, notwithstanding the fruitless results of Réaumur's examination, suffices to establish that fact. It is probable, however, that the phosphoric emanation from this and other species is only perceptible at certain seasons of the year, and this consideration may explain the discrepancy arising from M. Richard's observations. *F. candelaria*, Fab. (Plate CCXXIX. fig. 12), is a native of China and other eastern countries, and is very abundant in collections. It is known among us by the name of *Lantern fly*, and may be easily recognised by its long cylindrical snout, arched in an upward direction, its greenish reticulated elytra, and orange-yellow wings with black extremities. At night this insect glitters by thousands among the dark recesses of the Banyan tree, which

> ....to Indians known,
> In Malabar or Deccan spreads her arms,
> Branching so broad and long, that in the ground
> The bended twigs take root, and daughters grow
> About the mother-tree, a pillar'd shade
> High overarch'd, and echoing walks between.

And they are likewise observed to dance in perpetual motion around the outmost branches of the spreading tamarind, producing a brilliant and singularly beautiful effect. *F. Europæa*, Lat. (Stoll, *Cigales*, pl. xi. fig. 51), occurs in the south of France, Italy, and the islands of the Mediterranean. Its front assumes the form of a conical advancement, with three raised lines above and five below. The elytra and wings are transparent, with green reticulations. There are three raised lines on the thorax.[1]

GENUS OTIOCERUS, Kirby. Muzzle advanced. Simple eyes wanting. Two small appendages beneath each antenna.

GENUS LYSTRA, Fab. Head transverse, and without any prolongation in the form of muzzle. Two simple eyes. Second articulation of the antennæ granular, and almost round.

The species of this genus at first sight resemble small *Cicadæ*. The extremity of the body, in the females, is furnished with little bundles of cotton threads, beautifully white, with which, it is presumed, they surround their eggs. We are acquainted with many species from China, the East Indies, and South America. We shall here mention only *L. lanata*, Fab. (*Cicada lanata*, Lin.), of which the sides of the front are red, and the extremities of the elytra black, with points of blue. We receive it from Cayenne and the Antilles.

We shall here indicate a few genera, into the detailed history of which we cannot enter. The CYXII of Latreille resemble Lystræ, but the second joint of the antennæ is smooth and cylindrical. Under the appellation of TETTIGOMETRA, Latreille has separated certain insects analogous to the preceding, but with the antennæ lodged between the posterior and lateral angles of the head, and those of the anterior extremity of the thorax. The eyes are not projecting.[2] The preceding genera are provided with simple eyes; but in such as follow, these organs are wanting.

The species with large elytra, and the prothorax shorter in the middle than the mesothorax, compose the genus PÆCILOPTERA of Latreille and Germar (*Flata* of Fabricius).[3] In ISSUS, Fab. the prothorax is as long at least as the mesothorax; and the elytra, scarcely longer, or sometimes shorter, than the abdomen, are dilated at their base, and then narrowed.[4] Sometimes the antennæ are at least as long as the head, and are most frequently inserted in an inferior emargination of the eyes. The genus ANOTIA of Kirby resembles Issus in the insertion of the antennæ.[5] In ASIRACA of Lat. (*Delphax* of Fab.) the antennæ are inserted in an inferior emargination of the eyes, and are as long as the head and thorax united. Their first joint is usually longer than the second, and is compressed and angular. In DELPHAX, as constituted by Latreille, the antennæ are similar in their insertion, but they are never much longer than the head, and their first joint is much shorter than the following one, and without ridges. The simple eyes are apparent. The genus DERBE of Fab. is allied to Anotia. The species are little known. They are all exotic, and most of them come from South America.

B. *Cicadellæ*.

Antennæ inserted between the eyes. Latreille subdivides this portion of the family of Cicadariæ into the following genera.

He commences with the species which, with the exception of a few (the LEDRÆ), formerly composed the genus *Membracis* of Fabricius. The head is much inclined or lowered anteriorly, and prolonged to an obtuse point, or under the form of a clypeus, more or less semicircular. The antennæ are always very small, terminated by an inarticulate seta, and inserted into a cavity beneath the margin of the head. The prothorax is sometimes dilated and horned on either side, prolonged and restricted posteriorly to a point or spine, either simple or compound, sometimes elevated longitudinally along the back, compressed into a sharp edge or crest, and sometimes projecting and pointed forwards. The legs are scarcely spiny.

Hemiptera Homoptera.

a.

No apparent or exposed scutellum properly so called.

*

Tibiæ, especially the anterior, strongly compressed and foliaceous. Upper part of the head always forming a kind of semicircular clypeus.

Genus Membracis, Fab. Prothorax elevated, compressed, and foliaceous along the middle of the back.

Of this pretty numerous genus we shall notice only *M. foliata*, Fab. (Plate CCXXIX. fig. 14), which is of a blackish brown, the front advanced, flattened, the thorax marked by an arch and band of white. The latter part is greatly elevated, flattened laterally, forming a salient crest, advancing over the head, which it almost entirely covers, and terminated posteriorly by a point prolonged beyond the abdomen. The elytra are oval, longer than the wings. The legs are elongated, flattened, rather broad. The anterior tibiæ are shorter, of an oval form, and flattened. The native country is Cayenne.

Genus Tragopa, Lat. Prothorax presenting on each side a horn or salient point, without any intermediate elevation, and prolonging itself posteriorly into an arched projection of the length of the abdomen, and occupying the place of the scutellum.

This genus is composed of certain species from Brazil, which M. Latreille regards as analogous to *M. glabra*, *albimacula*, and *xanthocephala* of Germar.

* *

Tibiæ of the ordinary form, not foliaceous.

Genus Darnis, Fab. Posterior prolongation of the prothorax covering almost the whole, or the greater portion, of the upper part of the abdomen and elytra, and forming an elongated and arched triangle.[1]

Genus Bocydium, Lat. Elytra entirely or in greater part exposed, the posterior and scutellar prolongation of the prothorax being narrow, and more or less lanceolate or spiniform.

The *Centrotus horridus*, *trifidus*, *globularis*, *clavatus*, and *claviger*, of Fabricius, belong to this genus.

b.

Scutellum partially exposed, even although the prothorax is prolonged;—the posterior extremity of the latter offering a transverse suture, which distinguishes it from the scutellum.

Genus Centrotus,[2] Fab. Similar to *Membracis*, but the thorax is dilated horizontally, and covers only a part of the body.

C. *cornutus*, Fab. (*Cicada cornuta*, Linn. Plate CCXXIX. fig. 15), is of a blackish-brown, the thorax with a horn on each side, and prolonged posteriorly to a sinuated point of the length of the abdomen. This species measures about four lines in length. It occurs in France, and other parts of Europe, in woods, on ferns, &c. and is known by the name of *petit diable*. *C. genistæ*, Fab. is of an obscure brown, the thorax without horns, but terminated posteriorly by a straight sharp point, as long as the half of the abdomen. It is only half the size of the preceding, and occurs on the broom. It is called *demi-diable* by the French.

M. Latreille now proceeds to those species of which the head, if not upon a level with, is scarcely lower than, the prothorax, and is horizontal or slightly inclined when seen from above. The prothorax is neither elevated in the centre, nor posteriorly prolonged, and offers at most some lateral dilatations. The mesothorax presents itself under the form of an ordinary-sized triangular scutellum. The elytra are always entirely exposed, and the posterior tibiæ at least are spinous.

In several genera the thorax bears the form of an irregular hexagon, prolonged and narrowed posteriorly, and terminated by a truncation, serving as a support to the base of the scutellum, which it frequently receives into itself,—the truncated portion being concave or emarginate. In the genus Ledra, Fab. the vertex is triangular, and bears the ocelli. The antennæ are inserted upon or above an ideal line drawn from one eye to another. The head is very flat before the eyes, in the form of a transverse clypeus, arcuated and terminated in the centre of its anterior margin by an obtuse angle. All the under parts of the head are plane, or on the same level. The sides of the prothorax are raised in the form of rounded horns. The posterior tibiæ are much compressed, and as if margined exteriorly by a dentated membrane. The *Cicada aurita* of Linn., or *grand diable* as it is called by Geoffroy, belongs to this genus. In the genus Cercopis, Fab. the third joint of the antennæ is conical, and terminated by an inarticulate seta. Of this genus *C. sanguinolenta* is a well-known and ornamental British species, as is also *C. spumaria*, Linn. of which the larva inhabits a white foam frequent on the leaves and stalks of various plants, and called *frog-spittle* in England—*gowk-spittle* in our northern parts of the kingdom. The latter species is by some classed in the genus *Tettigonia*.

In other genera of Cicadariæ, which terminate our present family, the prothorax is scarcely if at all prolonged posteriorly, and terminates, at the height of the origin of the elytra, by a nearly straight line, the length of which is nearly equal to the breadth of the body. The scutellum, measured at the base, occupies a great proportion of that breadth. Here are ranged the genera Eulopa, Eupelix, Penthimia, Jassus, and Tettigonia properly so called.[3]

FAMILY II.—APHIDII.

These singular insects are distinguished from those of the preceding family by the tarsi, which have only two articulations, and by the antennæ, filiform or setaceous, longer than the head, and composed of from six to eleven articulations. Such as possess organs of flight have always two elytra and a pair of wings. The species are usually very small,—their bodies generally of a soft consistence, the elytra and wings nearly alike, or differing merely in size and thickness. They lay a prodigious number of eggs, and their mode of production is in other respects very remarkable.

In some the antennæ consist of from ten to eleven articulations, of which the last is terminated by a couple of setæ. These are leaping insects, and compose the genus Psylla of Geoffroy (*Chermes*, Linn.). They are known under the title of *faux-pucerons* to the French naturalists, as distinguished from the true Aphides after mentioned. They live on trees and various plants, by the juices of which they are nourished. Both sexes are winged. The body of the larvæ is usually very flat, the head large, the abdomen rounded posteriorly. Their feet are terminated by a small membranous vesicle, furnished beneath with a couple of hooks. The nymphs are distinguishable by four broad flat dorsal portions, which constitute the sheaths of the incipient wings and elytra. Several species are covered during both of those immature conditions

Hemiptera Homoptera.

by a white and cottony substance, disposed in flakes. Their fæces form threads or masses of a gummy and saccharine nature. Several species, by the wounds which they occasion to plants while sucking their juices, occasion the growth of peculiar excrescences on the buds and leaves, resembling gallnuts. Of these is *Psylla buxi* (*Ch. buxi*, Linn.), which is green with yellowish-brown wings. Mr Stephens has named a great many British species as belonging to this genus.[1] Latreille has founded the genus Livia upon a species which dwells among rushes (Plate CCXXIX. fig. 17). The antennæ are much thicker near the base than towards the extremity.

In other Aphidii the antennæ have only from six to eight articulations, of which the last is not terminated by a couple of setæ.

Some have the elytra and wings linear, fringed with hairs, and placed horizontally upon the body, which is of an almost cylindrical form. The rostrum is very small or indistinct. The tarsi are terminated by a vesicular article, unfurnished with hooks. The antennæ consist of eight granular articulations. Such are the species which form the genus Thrips of Linn. (Plate CCXXIX. fig. 18). These insects are very small, extremely active, and seem to leap rather than fly. When teazed, they raise and recurve the extremity of the abdomen, after the manner of the Staphylinidæ. They live among flowers and other parts of plants, and beneath the bark of trees. We may add, that although Latreille did not perceive in the organization of the mouth of these insects any characters essentially different from such as distinguish that organ among the other component parts of the homopterous Hemiptera,—yet M. Straus, who has studied the subject very laboriously, and with his wonted intelligence, is of opinion that the genus Thrips belongs in fact to the orthopterous order.

Others have the elytra and wings oval or triangular, without fringe, and inclined or tectiform. The rostrum is distinct. The tarsi are terminated by two hooks. The antennæ consist of from six to seven articulations. Such are the species which compose the great genus *Aphis* of Linn. which is now divisible as follows.

In the genus Aphis properly so called, the antennæ are longer than the thorax, of seven articulations, of which the third is elongated. The eyes are entire, and the abdomen is furnished with two horn-like projections at its posterior extremity. The species dwell together in society on various trees and plants, of which they suck the juices. They walk very leisurely, and cannot leap. The two horn-like processes just mentioned are hollow tubes, from which a drop of transparent liquid frequently exudes. It partakes of the property of sugar, and is much sought after by ants, who suck it with avidity from the living Aphides. This curious fact was first noticed by M. Boissier de Sauvages, and has since been amply confirmed by M. P. Huber. The desired liquor seems to be given out voluntarily by the aphis, when solicited so to do by a gentle tap from the ant's antennæ. A single aphis may be sometimes seen surrounded by three or four ants, all in the act of deriving from it a plentiful and nectareous meal.[2] The congregations of the Aphides consist, in spring and summer, of apterous individuals, and of nymphæ with undeveloped wings. All of these are females, which give birth to *living young, et sans accouplement préalable.* The males, which consist both of winged and apterous insects, are produced towards the end of summer, or during the autumnal season. They fecundate the last broods produced by the females first mentioned; which broods consist of apterous females, differing from their progenitors in requiring impregnation prior to the continuance of their kind. They lay *eggs* soon after the sexual intercourse, and these remain in the crevices of trees, &c. throughout the winter, and in spring produce the broods above alluded to, which are capable of producing living young, without assistance from each other. "L'influence d'une première fécondation s'étend ainsi sur plusieurs générations successives. Bonnet, auquel on doit le plus de faits sur cet objet, a obtenu, par l'isolement des femelles, jusqu'à neuf générations dans l'espace de trois mois."[3] M. Duvau has recently added some observations to those of Bonnet and Réaumur on this singular subject.[4] By this extraordinary process of production, vast multitudes are brought forth during a favourable season, and the injury to vegetation, by the absorption of the juices, and the obstruction of the natural pores, is consequently great. Réaumur calculates, that in the course of five generations, a single mother may be the means of producing 5,904,900,000! But fortunately they are liable to the attacks of numerous enemies, and are greedily devoured by many other insects. The larvæ of the genus *Hemerobius*, those of different dipterous species, and of the *Coccinellæ* or lady-birds, make the helpless Aphides their constant prey. We cannot here describe the species, but shall content ourselves by naming a few familiar examples. *Aphis rosæ* (Plate CCXXIX. figs. 19 and 20) is a small green species, very abundant on the younger shoots of roses, the flowering of which it seems to damage or destroy. Its hordes may be killed by dipping the affected branch into soapy water. *A. quercus* occurs on the oak, and is remarkable for the great length of its beak, which is at least three times as long as the body. It is of a brown colour. *A. fagi* is attached to the beech tree, and covers itself, as do many other species, with a white and cotton-like down, which exudes from its body. Including the genus *Eriosoma* of Leach, we have above fifty species of aphis in Britain. In the genus Aleyrodes,[5] Lat. (*Tinea*, Linn.), the antennæ are short, composed of six articulations, and the eyes are emarginate. *A. Chelidonii* of Lat. (*T. proletella*, Linn.) is found upon the celandine (*Chelidonium majus*), and other plants. It resembles a little moth. The larva is oval, flat, and shaped like a small scale. The nymph is fixed and enclosed in an envelope, so that its transformations differ from those of its congeners. Indeed the somewhat anomalous character of this insect has been the cause of its being described under a great variety of names.[6] Mr Stephens enumerates five British species, including the one just mentioned.[7]

FAMILY III.—GALLINSECTA.

The insects of this family seem to have only one articulation to the tarsi, and are generally so described. It

---

[1] *Systematic Catalogue*, part ii. p. 361.

[2] The viscous drops so frequent on the foliage of many trees, and commonly known by the name of *honey-dew*, is this secretion from the Aphides. We have seen it falling from a willow tree like a gentle and continuous shower, and ascertained its origin by discovering at the same time millions of these insects incrusting the upper branches, and each giving out from time to time a minute drop of nectareous fluid.

Hemiptera Homoptera.

is the opinion, however, of M. Dalman, that those parts consist of three joints, with a single hook at the extremity.[1] The males want the rostrum, and have only two wings laid horizontally on the body; their abdomen is terminated by a pair of setæ. The females are winged and provided with a rostrum. The antennæ are filiform or setaceous, and consist, for the most part, of eleven articulations. There are only nine in the males of the species described by M. Dalman. These creatures form the noted genus *Coccus* of Linn. commonly called cochineal insects. They are also known by the name of *Chermes*,[2] and their history and attributes are sufficiently remarkable.

We may frequently perceive on the branches of various trees multitudes of small oval or rounded bodies resembling scales, adhering closely to the wood, and presenting no indications of any external organs. These are insects of the genus Coccus, the *progallinsectes* of Réaumur. Their history was for a long period extremely obscure, and the species employed in commerce was even at one time regarded as a kind of grain. It was only towards the termination of the seventeenth century that M. Plumier clearly established their insect origin. We are indebted to Réaumur for a complete history of the life and transformations of the European kinds. The larvæ of both males and females, on first quitting the egg, are tolerably active, and run about among the leaves and branches. They are, however, so extremely small at that period, as not to be distinctly discernible without the aid of a microscope. They are flat, ovular, apterous, with short and indistinctly articulated antennæ. The males have no apparent organs of manducation, although the females are furnished with a small, extremely short, almost conical beak, inserted between the first and second pair of feet, nearly perpendicular in its direction, and composed of a four-jointed sheath containing a sucker of three pieces. It is with this instrument that they pump the juices of the leaves and tender stems. They also fix themselves from time to time for the purpose of changing their skin, and after arriving at a certain size, they become definitely fixed in some chosen spot, usually at the bifurcation of a branch, where they form a little nest, protected by a tapestry of cotton. They then attain the perfect state, and are apterous (we speak of the females) even in that otherwise complete condition. Their head is semicircular, their mouth is still formed of the beak which existed in the larva state, and the eyes are small. The thorax is not easily distinguished from the abdomen, the segments of which are distinct. When the insect has attained its full growth, its abdomen is found filled with a multitude of minute eggs. The larvæ of the males, though by no means rare, are much less numerous than those of the other sex. Their mode of sustenance, owing to the want of the sucker, is not distinctly known; but they increase in size, and after a time their skin hardens, and serves as a cocoon, in which they undergo their transformation to the nympha state. In the latter condition they are remarkable for the anterior pair of legs being directed forwards. Towards the beginning of spring these cocoons open at their posterior portion, and the perfect male insect comes forth stern foremost. It is of a more elongated form, with a round head furnished with two small eyes and a pair of rather long antennæ. The thorax is rounded, and has attached to it a pair of long wings, folded horizontally one over the other, and very delicately veined. (For a male Coccus see Plate CCXXIX. fig. 16; the female is shown by figures 21 and 22). The male is less than the female, and more active, although it uses its wings very sparingly. As soon as it attains the perfect state, it sets off in search of the other sex, which still remains fixed in the nest, as formerly mentioned. The oviposition of the female is another remarkable peculiarity in the history of these insects. Though excluded from the body, the eggs do not appear externally, but are made to pass beneath the abdomen, and between it and the cotton tapestry above alluded to. In proportion as the insect becomes empty, the lower surface of the abdomen approaches the upper one, so as to leave beneath the body a kind of arch or cavity for the reception of the eggs. The perfect female never stirs a step in the course of her life, but having laid her eggs she dies, and her body shrivels up and hardens, and thus forms a cocoon or covering for the incipient young. These, as soon as hatched, work their way from beneath the dead body of their parent, making their escape by its posterior extremity.

These curious insects are certainly hurtful to vegetation, by causing a too abundant transudation of their juices; and they consequently excite the jealousy of those who cultivate the finer trees, such as the peach, the orange, the olive, and the fig. Certain species attack also the roots of plants. But, upon the whole, the advantages which we derive from this genus of insect amply counterbalance whatever injuries it may occasionally inflict upon us. The species are very numerous. We shall here notice only a few of the more remarkable.

Of the kind called Kermes, is that known to naturalists by the name of *Coccus Ilicis*, of which the female attains to the size and form of a pea. It is of a violet-black colour, covered by a whitish powder. This species is common over the south of Europe on the evergreen oak, and appears to be widely distributed over many of the south-eastern countries of the ancient world. It occurs abundantly in Spain, where it attaches itself chiefly to the twigs and leaves of a small species of spiny-leaved oak, frequent in the southern parts of that romantic kingdom, especially on the slopes of the Sierra Morena. Many of the inhabitants of Murcia have no other means of subsistence than those procured by collecting the Kermes. Women are usually so employed, and they scrape the adhesive insects from the trees by means of their nails. Though supplanted over the greater portion of Europe by the introduction of the more famous cochineal (*Coccus cacti*), which is an American species, it is still extensively used in India and the Persian dominions.[3] It has been employed from time immemorial to impart a blood-red or crimson dye to cloth, and was known to the Phœnicians by the name of *Thola*. It was called coccus (Κοκκος) by the Greeks, and kermes or alkermes by the Arabians. According to Beckman, the epithet *vermiculatum* was applied to it during the middle ages, when its insect origin came to be generally understood, and hence is derived our English word vermilion. The French term *cramoisi* is evidently from the Arabic. It is supposed to have been by means of this substance that the curtains of the tabernacle (Exodus, xxvi. &c.) were dyed of a deep red (which the word scarlet then implied, rather than the colour so named in more modern days, which was unknown in the reign of James I. when our Bible was translated); and from the same source have been derived the imperishable reds of the Flemish tapestries. The scarlet afforded by cochineal was unknown in its highest perfection till the year 1630, when the singular power of the oxide of tin in exalting its colours was discovered in Holland; it was soon after communicated to one of the celebrated MM. Gobelins of Paris, and may have contributed to the perfection of their tapestries.[1] Since the preparation of Morocco leather has been established in this country, cochineal has been employed to produce the beautiful colour of what is called red morocco; but in Persia, Armenia, Barbary, and the Greek islands, a similar colour was originally produced by the use of either kermes or lac.[2] The colouring matter of kermes is regarded by Dr Bancroft as identical with that of cochineal, but combined with some astringent matter derived from the tree on which it feeds.

---

[1] See his Memoir in Swedish,—*Om nagra svenska arter of Coccus*, Stockholm, 1826.

[2] Be it remembered, however, that the genus *Chermes* of Linn. corresponds to *Psylla* of Lat. already described, and not to our present species, which are the true *Kermes* of Geoffroy, Réaumur, and Olivier.

[3] Kirby and Spence's *Introd. to Ent.* and Bochart's *Hierozoic.*

The substance called *lac* is also the produce of an insect of the Coccus kind. It is collected from various trees in India, where it is used in the fabrication of beads, rings, and other ornaments of female attire. When mixed with sand it forms grindstones; and, added to ivory black, and previously dissolved in water with a little borax, it composes an ink which, when dry, is said to be capable of resisting a considerable degree of damp or moisture. In this country, according to the different states in which it is imported, it is called stick-lac, seed-lac, lump-lac, or shell-lac. It is chiefly used in the making of varnishes, japanned ware, and sealing-wax, although during late years it has been applied to a still more important purpose, as originally suggested by Dr Roxburgh, that of a substitute for cochineal in dyeing scarlet. The first preparations from it with this view were made in consequence of a hint from Dr Bancroft; and large quantities of a substance termed *lac-lake*, consisting of the colouring matter of stick-lac, precipitated from an alkaline lixivium by alum, were manufactured at Calcutta, and sent to this country, where at first the consumption was so considerable, that in the three years previous to 1810 the sales at the India house equalled in point of colouring matter half a million of pounds weight of cochineal.[3] "More recently, however, a new preparation of lac-colour, under the name of *lac-dye*, has been imported from India, which has been substituted for the lac-lake, and with such advantage, that the East India Company are said to have saved in a few months L.14,000 in the purchase of scarlet cloths dyed with this colour and cochineal conjointly, and without any inferiority in the colour obtained."[4] The only mordant formerly used with kermes was alum, and the colour communicated was blood-red; but Dr Bancroft ascertained, that with the solution of tin used with cochineal it was capable of imparting as brilliant a scarlet as that dye, and one perhaps more permanent. It must be borne in mind, however, that as ten or twelve pounds of kermes contain no more colouring matter than a single pound of cochineal, the latter at its ordinary price is, after all, the cheapest.

Several other curious and valuable products are obtained from insects belonging to the genus Coccus, or to one nearly allied in its natural character and attributes. The *pe-la*, for example, or white wax of the Chinese, is derived from an insect, apparently a Coccus, described by the Abbé Grozier; and a non-descript Indian species produces a wax analogous to pe-la, first noticed by Dr Anderson under the name of white lac. It is obtained in great quantities in the vicinity of Madras; but Dr Pearson's experiments do not countenance the idea, at one time rather sanguinely entertained, that it might be advantageously used for making candles.[5] Geoffroy long ago attributed to a species of kermes the faculty of producing a sugary substance, of a white colour, resembling manna; and Captain Frederick has described an article of that nature under the name of *Gez*, found in Persia and Armenia; but he seems doubtful whether to attribute to it an animal or a vegetable origin.[6] More recently, however, General Hardwicke has described an Indian insect, under the name of *Chermis mannifer*, of the size of the domestic bug, and of a flattened oval form, with a rounded tail. From its abdomen a quantity of saccharine substance is exuded, and assumes the form of a bunch of feathers, with a consistence like that of snow. These insects are found on the branches and leaves of trees in millions, and they there produce this feather-like secretion, till it becomes elongated, and, dropping on the leaves, hardens upon them into a substance resembling the most beautiful wax.[7]

Of the European species, in addition to *C. Ilicis*, already described, we may mention *C. adonidum*, now naturalized in our hot-houses, where it is very destructive, and *C. polonicus*, which yields a colouring matter almost as beautiful as the Mexican cochineal; it attacks the roots of *Scleranthus perennis*, and other plants, and is still used as a dye in Russia.

Before closing this branch of our subject, we must devote a few lines to the cochineal insect properly so called, the *Coccus cacti* of naturalists (Plate CCXXIX. figs. 16, 21, 22). This species, so important in a commercial point of view, and in relation to our arts and manufactures, is a native of Mexico, where it was assiduously cultivated at a period long anterior to the European conquest of that country. We shall not describe its appearance, as that will be better understood by an inspection of the figures just referred to. There are several varieties, named in general from the provinces where they are bred; and of these, that called Mastique or Mèsteque is regarded as the best. It is cultivated on a tree called Nopal by the Indians (*Cactus cochenilifer*, Linn.) and its colour is by some attributed to the juices of that plant. It is the female insect that is so highly valued for the incomparable beauty of its colour. It is imported to Europe in the form of a little grain, convex on one side, concave on the other, and exhibiting traces of the abdominal segments. In the year 1736 there was sent to Europe about 700,000 pounds weight of this minute creature, a quantity worth L.700,000 sterling. Humboldt states the quantity imported about the period of his inquiries to have been 32,000 arrobas, worth in South America L.500,040 sterling,[8]—"a vast amount to arise from so small an insect, and well calculated to show us the absurdity of despising any animals on account of their minuteness."[9] Dr Bancroft calculates the annual consumption of cochineal in Great Britain at about 750 bags, or 150,000 pounds weight,—worth L.375,000 sterling at recent prices. The natives of those districts in which the cochineal is reared form plantations of the nopal tree near their dwelling-houses. It grows freely from cuttings, and the latter are fit for the reception of the insect in eighteen months. Eight or ten females are put into a small nest formed of tufts of a thread-like substance collected from a species of palm, or of any other cottony matter. These nests are attached to the spines of the nopal, upon the side facing the rising sun, and the insects are placed in them about the middle of October, a period at which good weather usually commences in Mexico after the rains. The eggs are soon laid and hatched, and the progeny spread in vast numbers over the plant, each female producing upwards of a thousand young. According to M. Thierry de Menonville,[1] six generations are produced in a year, and they might be collected at all seasons, but for the destruction produced among them by the periodical rains. The first collection takes place about the middle of December, and the last in the month of May. They are detached by means of a knife with the edge blunted, to prevent injury to the nopal tree. When the first gathering is made, the nests are taken away, and the dead females (those placed on the nopal in October) are likewise picked off. These are lighter and less valuable than such as are taken off alive and full of young; the former losing three fourths, the latter two thirds, during the process of drying. As soon as dried, however, both kinds may be kept for any length of time, without any further loss of either weight or colour. They are killed by different processes. Some put them in a basket, which they dip in boiling water, and afterwards dry them by exposure to the sun; others place them in an oven, or on plates of heated iron. The various external colours of the insect, as we afterwards see it in Europe, depend upon the mode of putting it to death. Those which have been killed by being dipt in hot water (the method regarded as the best), lose a portion of the white powder with which they were previously invested, and acquire a brownish-red colour. When so treated, they pass under the name of *renagrida*. When killed in an oven they retain the white powder, remain externally of a grey colour, and are called *jarpeada*. Such as are placed on plates of heated iron become of a blackish hue, and are then named *negra*. When cochineal insects are forced from the tree, they speedily die, even if no further violence is offered them; because their sucker, being fixed in the wood, is unavoidably dislocated and broken off by the act of removal. It is necessary, however, to put them to death, because they might otherwise live for a short time, and meanwhile produce their young, the loss of which would diminish the quantity of colouring matter.

The other most frequent variety of cochineal is called *sylvester*, on account of its being commonly collected from a species of cactus which grows wild, or without culture. It is of smaller size, and much less valuable in relation both to the amount and quality of the colour which it yields. We have not yet ascertained to our own satisfaction whether it is a mere variety or a distinct species. Although it occurs naturally upon a wild spiny cactus, it is also cultivated upon the nopal or garden species, for the sake of the greater facility of collection. So great indeed is the difference in this point, that in one day a single labourer will gather from the latter a quantity which, when dry, will amount to the weight of three pounds,—whereas from the former the most persevering hand will not obtain in that time much more than a couple of ounces. Moreover, when cultivated on the garden nopal, the *sylvester* cochineal attains to as large a size as the *mastique*.

Various attempts have been made to introduce the culture of the cochineal into our eastern possessions, although these, so far as we are informed, have not yet been attended with any marked success. The old Spanish government manifested great jealousy on the subject; and we are not aware that the true kind has been yet imported, although the court of directors at one period offered a reward of L.6000 to whoever should effect its introduction to India. Colonel Bory St Vincent informs us that attempts have recently been made, and with a fair prospect of success, to effect its cultivation near Malaga, in Spain.[2] We shall conclude our sketch by observing that considerable care is requisite to preserve these insects from the attacks of their natural enemies, of which one of the chief is the larva of a species of Coccinella, which sucks them to death, and leaves nothing but the skin. A very destructive foe is also described as being a caterpillar, of an inch in length, and the thickness of a crow-quill, which, it is said, would soon destroy the race if allowed to continue its attacks without any interference on the part of the higher powers.[3] It is said that a species of *Ptinus* also feeds upon them freely. Besides these direct enemies, there is another insect, with the exact nature of which we are not acquainted, which lives in common with the cochineal upon the juices of the nopal, and by so doing greatly interferes with the health and progress of the more valuable species. Among its larger, if not more formidable enemies, we may mention a mouse, which is said always to prefer the mastique or finer cochineal to the sylvester or wild species, because the cottony matter with which the latter is invested produces discomfort by entangling in its teeth. Both kinds are moreover subjected to the attacks of numerous birds.

ORDER IV.—NEUROPTERA.[4]

Distinguished by four naked or transparent wings, reticulated or interlaced by a delicate network, and usually of the same size as well as texture. The mouth is adapted for mastication, that is, furnished with mandibles and true maxillæ, and never assumes the tubular form. The abdomen does not possess a sting, and is rarely provided with an ovipositor. The antennæ are usually setaceous, and composed of numerous articulations. The head is furnished with two or three simple eyes. The thorax is formed of three segments, intimately united to each other, though perceptibly distinct from the abdomen; the first of these segments is usually very short, and in the form of a collar. The number of joints of the tarsi varies. The form of the body is for the most part elongated, and its texture rather soft and delicate. The abdomen is always sessile. Many of the species are carnivorous, both in the larva and perfect state.

This beautiful and very varied order has been divided into two by Mr Kirby, by the separation of the genus *Phryganea* of Linn., which the English naturalist raises to the rank of an order under the name TRICHOPTERA. It might also have simplified the characters of the order if we had left in it only those which possess reticulated wings; but as some of the latter exhibit a difference in the texture of the organs of flight, it is difficult to assign rigorous characters to the neuropterous tribes, if we attach a high importance to the wings. "Of all the Linnæan orders," says Mr Kirby, "this appears to consist of the most discordant tribes; so that it seems next to impossible to construct a definition that will include them all, unless indeed we admit M. Latreille's idea, adopted by Mr Macleay, that a varied metamorphosis is its essential character; or, to speak more largely, variety itself seems the characteristic of the insects composing it in every state, and there is scarcely a common distinctive character in their perfect state, upon detecting which in any individual, you may exclaim—this is a neuropterous insect."[1] The neuropterous species, however, may be readily distinguished from the orthopterous and hemipterous kinds by the greater difference of consistence in the two latter between the upper and under wings. The Hymenoptera, again, have generally much longer maxillæ—serving rather to suck the juices than to bruise the more solid portions of the substances on which they feed. The scale-covered wings of the lepidopterous order prevent their being confounded with our present subjects; while the Diptera are easily distinguished by the absence of the lower wings, and the different structure of the organs of manducation.

---

[2] *Annal. des Sciences Nat.* t. viii. p. 105.

[3] We scarcely think that the creature above alluded to can be a caterpillar properly so called, that is, the larva of a lepidopterous insect.

[4] ODONATA, and the majority of SYNISTATA, of Fabricius.

The mouth in the neuropterous order is generally composed of a labrum and a labium, of two mandibles, and a pair of maxillæ. The latter organs are very sharp and strong among the *Libellulæ*, which prey on other insects, but extremely small or almost imperceptible in the *Ephemeræ*, which, as their name implies, are very short-lived, and take no nourishment in the perfect state. The palpi are very short in the former tribes, but exceedingly long among the *Myrmeleones*. Although the antennæ, in the majority, are filiform or setaceous, they are terminated by an elongated club in those last named; while in the genus *Ascalaphus* they are very long and slender, and terminate in a little button, resembling those of many Lepidoptera. The wings are sometimes tectiform or incumbent, sometimes stretched out horizontally. Though frequently alike in size, they occasionally differ from each other. Thus in the genus *Nemoptera* the under pair are very long and narrow, while in some Ephemeræ they are almost obliterated.

In the larva and nympha states these insects are either terrestrial or aquatic, according to their kinds. In the former case some dwell beneath the bark of trees, others move about on twigs and branches, making an unresisting prey of Aphides; while a certain number inhabit sandy soils, where they excavate insidious pit-falls, and seize upon whatever insects venture within the circle of their treacherous toils. The aquatic species dwell in their earlier states in ponds and marshes, and in the shallower and more sheltered parts of lakes and rivers. They then respire by means of organs which exhibit a strong analogy to the gills of fishes, but which Latreille recognises only as exterior tracheal appendages, named false branchia. Many construct very ingenious cases of small stones, shells, and twigs of water-plants, in which they move about in their watery element.

The Neuroptera are, in general, insects of an extremely elegant deportment. They fly with great facility, and are not unfrequently adorned by agreeable and varied colours. Though almost all carnivorous as larvæ, their habits differ greatly in the perfect state. Some undergo a semi-metamorphosis,—others are completely changed,—but all the larvæ are provided with six-hooked feet, which they usually employ in their search for food. Latreille divides the order into three families, which present the following succession of natural affinities. 1*st*, Carnivorous insects, subject to a semi-metamorphosis, with aquatic larvæ; 2*d*, carnivorous insects, subject to a complete metamorphosis, with terrestrial or aquatic larvæ; 3*d*, carnivorous or omnivorous insects, terrestrial, with semi-metamorphosis; 4*th*, herbivorous insects, subject to a complete metamorphosis, with aquatic larvæ, which construct portable domicils. He terminates with such as have the wings the least reticulated, and which bear a resemblance to Phalenæ or Tineites.

FAMILY I.—SUBULICORNES, Lat.

These consist of the *Odonata* of Fabricius, and the genus *Ephemera*. The antennæ are subulate or awl-shaped, scarcely longer than the head, and consist at most of seven articulations, of which the last is setiform. The mandibles and maxillæ are entirely covered by the labrum and labium, or by the anterior or prolonged portion of the head. The wings are always much reticulated, separate, sometimes horizontal, sometimes raised perpendicularly. The inferior pair, though often as large as the superior, are in some instances much less, or even entirely wanting. The real eyes are large and projecting, and have from two to three stemmatic eyes placed between them. They feed on living prey, and pass their earlier states beneath the waters. The larvæ and nymphs exhibit a form somewhat similar to that of the perfect insects, and respire by particular organs placed along the sides or at least the extremity of the abdomen. They creep up the stalks of plants, or otherwise leave their moist abodes, before undergoing their final transformation.

In the great genus Libellula of Linn. (Plate CCXXX. figs. 1, 2, 3, 4, 6), the mandibles and maxillæ are corneous and very strong, and are covered by the labrum above and by the labium below. The tarsi have three articulations. The wings are nearly of equal size, and the posterior extremity of the body is terminated simply by hooks or by foliaceous appendages.

The light and graceful form of these insects, their beautiful and varied colours, their large and lustrous wings, and the hawk-like velocity with which they pursue their flying prey, render them objects of our frequent attention, and easy to be recognised. Our present observations apply to all the component parts of the great and unrestricted genus just named. We shall afterwards give the specialities of the minor groups. The eyes of the Libellulæ, or dragon-flies in general, are large and lateral; the stemmata are placed upon the vertex. The antennæ are inserted on the front, behind a vesicular elevation, and are composed in the greater number of from five to six articulations, or at least of three, of which the last is composite, and attenuated in the form of a style. The labrum is arched and semicircular; the mandibles are of a scaly texture, very strong and toothed; the maxillæ are terminated by a piece of the same consistence, dentated, spinous, and ciliated on the inner side, with a palpus of one articulation on its back, representing what is called the *galea* in the orthopterous tribes. The labium is large, arched, and trifoliate, the two lateral foliæ being in fact palpi. There exists a kind of epiglottis, or vesicular and longitudinal tongue, in the interior of the mouth. The abdomen, always considerably elongated, varies in its contour, being in some cylindrical, in others compressed, and occasionally flattened. It is terminated in the males by two lamellar appendages, which likewise vary in form according to the species. The legs are short, and directed forwards. "Le dessous du second anneau de l'abdo-

---

[1] *Introduc. to Ent.* vol. iv. p. 371.

men renferme, dans les mâles, leurs organs sexuels, et, comme ceux de la femélle sont situés au dernier anneau, l'accouplement de ces insectes s'opère différemment que dans les autres. Le mâle, planant d'abord au-dessus de sa femélle, la saisait par le col, au moyen des crochets de l'extrêmité postérieure de son ventre, et s'envole ainsi avec elle. Au bout d'un temps, plus ou moins long, celle-ci se pretant a ces desirs, courbe en dessous son abdomen, et en applique l'extrêmité sur les parties du mâle, dont le corps est alors courbé en forme de boucle. La copulation a souvent lieu dans les airs, et quelquefois encore sur les corps où ces insectes sont posés."[1] The female deposits her eggs on aquatic plants, by plunging her posterior extremity beneath the water.

The larvæ and nymphs are aquatic. The former have no wings, the latter exhibit them in a rudimentary state (Plate CCXXX. figs. 1, 3). The head in these early stages is remarkable for the singular piece which corresponds to the labium. It assumes the form of a mask, and covers the mandibles, the maxillæ, and almost all the under parts of the head. It is composed of, 1*st*, a principal triangular piece, sometimes arched, sometimes flat, named *mentonnière* (or chin-cloth) by Réaumur, which articulates by means of a hinge with a pedicle or kind of handle attached to the head; 2*d*, of two other pieces inserted at the lateral and inferior angles of the preceding, moveable at their base, transverse, and either in the form of wide and dentated plates, resembling shutters in their nature, and the mode in which they close the mouth, or analogous to little hooks or claws. To that portion of the mask where the *mentonnière* is articulated with its pedicle, or the knee, and which appears to terminate it inferiorly when the mask is bent or folded upon itself, Réaumur applied the term *mentum*. The insect unfolds and extends this peculiar apparatus with great promptitude, and seizes its prey with the pincers of the superior portion. These creatures live for ten or eleven months in the water, during which period they several times cast their skin. When the nymphs are ready to assume their final change, the form and position of the wing-cases undergo an alteration. They then leave the water, become dry and crisp, the skin of the thorax bursts asunder, and the winged insect issues forth under a different and much more ornamental aspect. The name of *Demoiselles*, by which many of them are known to our continental neighbours, attests the impression produced by their graceful forms or elegant movements. These Demoiselles always come out of the water head foremost; but no sooner have they burst their casements than they turn themselves round, and hang for a time with their head downward, being prevented from falling by the hinder segments of the abdomen being still entangled in and adhering to the skin of the nymph. After a time the young aspirant again turns round, and seizing the anterior portion of the cloven skin with its claws, it finally succeeds in dragging itself forth from its former dwelling. The wings, however, are as yet narrow, thick, and closely folded, just like a leaf during the bursting spring. After another hour or two they become firm, consistent, and extended both in length and breadth, and the gay and gorgeous creature, launching buoyantly into the air, becomes the tyrant of the insect world.

M. Poe, who paid particular attention to the entomology of Cuba, informed Latreille that, at a certain season of the year, the northern winds sweep an innumerable host of a species of dragon-fly into Havannah and its environs.[2]

The Linnæan genus LIBELLULA is now divided into three.[3] In LIBELLULA[4] proper (Plate CCXXX. fig. 2), the wings are extended horizontally in repose, the head is almost globular, with the eyes contiguous or approximate. There is a vesicular elevation, with a stemmatic eye on each side upon the vertex; the other stemmatic eye is larger, and placed anteriorly. The central division of the labium is much smaller than the lateral ones, which unite above by a longitudinal suture, and exactly close the mouth. The abdomen is usually ensiform, and flattened. The larvæ and nymphs (ibid. fig. 1) have five appendages to the posterior extremity of the abdomen, which combine to form a pointed tail; their body is short, and the part named *mentonnière* by Réaumur is arched in the form of a helmet, with the two lateral pieces in the form of shutters. We may mention *L. depressa*, Linn. (the species figured), as a British example of the genus. In ÆSHNA, Fab. the species resemble the preceding in the position of the wings and the form of the head, but the posterior stemmatic eyes are placed upon a simple transverse elevation or keel. The intermediate lobe of the labium is also larger, and the other two are distant, and armed with a very strong tooth, and a spinous appendage. The abdomen is always narrow and elongated. The form of the larvæ and nymphs is also more lengthened than that of the same states in Libellulæ. The mask is flat, and the two pincers are narrow, with a moveable nail at the end. The abdomen, in their early states, is also terminated by five appendages, one of which, however, is truncated at the point. *L. grandis*, Linn. the largest and one of the swiftest and most powerful and predaceous of the British species, belongs to this genus. In AGRION,[5] Fab. (Plate CCXXX. fig. 6), the wings are held perpendicularly in repose, the head is transversal, and the eyes distant. The form of the labium is analogous to that of Æshna, but the middle lobe is divided into two as far as its base. The third joint of the lateral lobes is in the form of a membranous ligula. The antennæ seem to be composed of only four joints. The front presents no vesicle, and the stemmatic eyes are of nearly equal size, and disposed triangularly on the vertex. The abdomen is very slender or even filiform, and, in some foreign species, of extraordinary length. That of the female is furnished with serrated laminæ at its posterior extremity. The form of the body in the larva and nympha states of this genus is likewise long and slender, and the abdomen is terminated by three fin-like plates (ibid. fig. 3). The mask is flat, the upper extremity of the *mentonnière* being raised to a point in some, and forked or sloped in others; the pincers are narrow, but terminate in several dentations resembling hands. The species are very numerous. *A. virgo* has dark-coloured wings, and a lustrous metallic body, varying from golden green to greenish blue. Its flight is irregular and rather heavy. To this genus also belong the small pale-coloured kinds, annulated with black, and presenting a considerable range of variation even among individuals of the same species, besides the more fixed distinctions of a sexual character.

---

[1] *Règne Animal*, t. v. p. 237.

[2] *Ibid.* t. v. p. 238.

[3] The structure of the eyes in dragon-flies is described by Cuvier in the *Mém. de la Soc. d'Hist. Nat. de Paris*, t. i. In addition to the ordinary systematic works, the student of the species should attend particularly to a monograph on European Libellulæ, published in the *Horæ Entomologicæ* of M. Toussaint de Charpentier, another monograph on the same by M. Vander Linden, and a memoir by the latter author on the species which occur in the territory of Bologna.

[4] Named probably from the Latin *Libellus*, a little book, on account of the page-like expansion of the wings.

[5] From ἄγριος, *cruel* or *ferocious*.

In the other Neuroptera of the family Subulicornes the mouth is entirely membranous or very soft, and composed of not very distinguishable parts. Their tarsi consist of five joints. The inferior wings are much smaller than the upper ones, and are even sometimes wanting. The abdomen is terminated by two or three setæ. They form the old genus EPHEMERA[1] of Linn., Plate CCXXX. figs. 5, 7, and 9.

In these frail and fleeting insects the body is very soft, long, and tapering, and terminates as above mentioned. Their antennæ are very small, and composed of three articulations, of which the last is very long, and in the form of a conical thread. The anterior portion of their head projects in the manner of a clypeus, is frequently carinated and emarginate, and covers the mouth, of which it is difficult to distinguish the structure, on account of the slight development of its parts, and the softness of their texture. The Ephemeræ in repose carry their wings almost always in a perpendicular position, or a little inclined backwards. The legs are slender, with very short tibiæ, frequently confounded with the tarsi, which often exhibit only four joints, owing to the evanescence of the first; the two hooks of the last are much compressed into the form of a little pallet. The two anterior legs are much longer than the others, inserted almost beneath the head, and extended forwards. These insects usually make their appearance in the winged state towards the evening in fine summer weather, and sometimes in such abundance, that in certain districts of France cart-loads of them have been gathered from the ground, and employed as manure. *E. albipennis*, in particular, a species, as its name implies, remarkable for the whiteness of its wings, sometimes rises and falls in such quantities by the banks of rivers, as to thicken the air and whiten the surface of the ground,—reminding one, even in the verdurous and leafy summer, of

> The flaky weight of winter's purest snows.

The males are distinguished from the females by a pair of articulated hooks, and their fore legs and caudal appendages are likewise longer. Although strictly ephemeral in their final state, they have rather a more extended term of life than usual in their subaqueous abodes, where they are said to live and prosper for two or three years. In the larva state the antennæ are longer than afterwards; the stemmatic eyes are wanting; the mouth presents two horn-like projections, which are regarded as mandibles; the abdomen is furnished on each side with a range of laminæ or leaflets, usually united at the base in pairs. These last-named parts are a kind of false branchia, on which the tracheal ramifications are extended, and which serve not only for the purposes of respiration, but also for those of locomotion. The tarsi have only a single hook at their extremity. The abdomen is terminated by setæ, of the same amount as in the perfect insect. The nymphs differ from the larvæ chiefly in being possessed of little sheaths or wing-cases (Plate CCXXX. fig. 10). When *ripe*, they leave the waters, and undergo their final transformation, pretty much after the manner of the Libellulæ already described, although more rapidly. One singular characteristic, however, attends their winged condition, from which the other tribes are free; they cast off a complete envelope or skin, including that even of the limbs, setæ, and antennæ, almost immediately after they have attained the perfect state, or at least what Mr Curtis has well named the *pseudo-imago*. While following the delightful pursuit of angling, both along our own unrivalled streams, and by the banks of foreign waters, we have frequently had our fishing panier and the rims of our hat covered by a pearly layer of these ghost-like exuviæ, and it proved extremely interesting to witness what we had often previously perused in the accurate pages of Réaumur. Swammerdam, who had long ago observed and described this singular moulting, seems to think that the male sex is alone subjected to it. The manners and metamorphosis of these insects have been minutely detailed by the laborious author just named, in his *Biblia Naturæ*, as well as by Réaumur and Degeer, in their respective *Mémoires* on the natural history of insects. The angler recognises them under the name of May-flies,—an imitation of which, during the early part of the trouting season, is deemed a lure not to be resisted by the finny race. We cannot here describe the species in detail. We have figured several different kinds on Plate CCXXX. Some have four wings, figs. 5 and 9; others have only two, fig. 7. Of the latter the eyes are sometimes very singularly constructed, being double, or two on each side, one above the other, as shown by fig. 8 of the same plate.

FAMILY II.—PLANIPENNES.

Latreille here includes those neuropterous species of which the antennæ, always composed of a great number of articulations, are considerably longer than the head, without being styliform or awl-shaped. The mandibles are very distinct, and the under wings, almost equal to the superior ones, are extended, or simply folded beneath at their inner margin. The wings are very generally much reticulated and naked, with the maxillary palpi for the most part filiform, or a little larger at the extremity, shorter than the head, and composed of from four to five articulations. These insects are divisible into five sections, which compose, in relation to their natural habits, an equal number of small sub-families, as follows.

SECTION 1ST, PANORPATÆ.

Characterized by five articulations to all the tarsi, and by having the anterior extremity of the head prolonged and narrowed, in the form of a beak or proboscis. These constitute the old genus *Panorpa* of Linn., commonly called scorpion-flies, probably from the peculiar turning up of their tails (Plate CCXXX. figs. 13 and 20). The antennæ are setaceous and inserted between the eyes. The clypeus is prolonged into a corneous lamina, arched beneath for the reception of the mouth. The mandibles, maxillæ, and labium, are almost linear (Plate CCXXX. fig. 16). The palpi, varying in number from four to six, are filiform; those of the maxillæ do not distinctly present more than four joints. The body is elongated, the head vertical, the first segment of the thorax usually very small, and in the form of a collar. The abdomen is conical or almost cylindrical. In several species the sexes are very dissimilar. Naturalists do not as yet appear to have acquired any knowledge of their transformations. They are now divided into the following genera: NEMOPTERA,[2] (Plate CCXXX. fig. 11), BITTACUS, PANORPA proper (ibid. fig. 13), and BOREUS. The type of the last-named genus, and the only species known, is the *Panorpa hyemalis* of Linn. a small insect scarcely a line in length, of a cupreous black colour. It lives among moss in the northern parts of Europe, and is also found in the Alps, not far from the region of perpetual snow.

---

[1] Named, in allusion to the seeming shortness of their lives, from εφημερος, *that which lasts a day.*

[2] From νημα, *a thread*, and πτερα, *wings.*

SECTION 2D, MYRMELEONIDES, Lat.

These are also characterized by five articulations to all the tarsi; but they differ from the preceding in not having the head prolonged in the form of a beak or proboscis. The antennæ are gradually enlarged, or have a globular or button-like termination. The head is transverse, vertical, and exhibits no stemmatic eyes. The ordinary organs of vision are round and projecting. The mouth is furnished with six palpi, of which the labial are usually longer than the others, and somewhat inflated at the extremity. The palate of the mouth is raised in the form of an epiglottis. The first segment of the thorax is small. The wings are equal, elongated, tectiform, or incumbent. The abdomen is generally long and cylindrical, with two projecting appendages at the extremity in the male sex. The legs are short.

These insects affect warm places, and are consequently more frequent in the southern countries of Europe than in the chilly regions of the north. They rest on plants, and generally remain quiescent during the day. The nymphs are inactive; but the generality of the perfect insects are well endowed with the power of flight. They form the old genus *Myrmeleon* of Linn., which Fabricius and Latreille have divided into two.

In MYRMELEON[1] proper (Plate CCXXX. fig. 12), the antennæ are short, gradually thickened or almost fusiform, and hooked at the extremity. The abdomen is long and linear. The singular larva of one of these insects (ibid. fig. 14) has been attentively studied by Poupart, Vallisnieri, Roesel, Réaumur, and others. It is rather more than half an inch in length, of an oval depressed form and greyish colour. It feeds chiefly on Solomon's emblem of industry, and has hence received the name of *Formica-Leo* or lion-ant. Its head is very small, but armed with two strong and lengthened mandibles, serrated on the inner side, and pointed at the end. These parts look rather like a pair of horns than organs of manducation; but it is with them that the larva seizes upon its prey; and as they are pierced at the extremity, they no doubt also act as suckers. As its form does not admit of active locomotion, nature has made amends by endowing this insect with admirable instinctive skill and cunning. It constructs, in a dry or sandy soil, a funnel-shaped excavation, the sides and edges of which are loose and crumbling, and at the bottom of which, with body closely covered, but with ever-ready jaws projecting upwards, the insidious larva lies concealed. No sooner does an industrious ant, laden perhaps with its republican provision, approach the edge of the unsuspected slope, to it as dangerous as a volcanic crater or avalanche of snow, than the finely poised sand immediately gives way, and the persevering citizen, rolling to the bottom, is instantly seized and sucked to a shadow by the lurking tyrant. The dead body is ere long tossed by a jerk of the head beyond the immediate boundaries of the dwelling, probably because it is by this time useless, or, as some French naturalist has expressed it, "pour que son cadavre n'épouvante pas les autres fourmis qu'il attend." There are tartars, however, among Myrmeleons as well as men; and it sometimes happens that a large and vigorous winged insect, such as a wasp, bee, or beetle, tumbles head foremost into the pit. "When Greek meets Greek, then comes the tug of war;" and when a lion-ant has the tail of a wasp in his mouth, there is no saying exactly how the combat may end. The one is furnished with jaws tenacious as well as strong,—but he bears no "charmed life;" while the other is armed with a weapon which the dews of heaven cannot rust, and compared with the keenness of which the brightest sword in Damascus is as a broken foil. In these doubtful, though, to one or other of the parties, eventually disastrous circumstances, the result at last is, that either the lion-ant is dragged out of his den and stung to death, or dropped upon the ground and left a prey to birds, or that the winged insect is maimed, disabled, drawn into the sand, and slain. If an insect incapable of flight, or from its situation unable to use its wings, but of larger size than the Myrmeleon deems it prudent at once to seize upon, chances to fall into the snare, it is overwhelmed in its attempts to re-ascend, by repeated showers of sand, which its enemy directs upon it with unerring aim. No sooner, however, is the strength of the toiling and exasperated Sisyphus at least in part exhausted, than he too is seized upon, and sucked to death. The lion-ant makes use of its head as a catapult or instrument of war, with which to shower the sand upon its astonished prey. This singular larva is capable of enduring a very long-continued fast. When it has attained to the natural term of its increase, which requires the lapse, it is said, of nearly a couple of years, it weaves a white cocoon, by means of two spinners placed at the posterior extremity of the body, of a rounded form and satin lustre, but covered with grains of sand. In this it undergoes its transformation to the nympha state (Plate CCXXX. fig. 15). The perfect insect bursts from its silken tomb in the course of from fifteen to twenty days. We are acquainted with many species of the genus. Besides the one of which we have just now sketched the history, and which is the *Myrmeleon formicarium* of systematic writers, another noted species, named *M. Libelluloides*, occurs in the south of France. It is a very large insect, measuring from four to five inches between the tips of the extended wings, and was described as a *Hemerobius* by Linnæus. It is the *Libella turcica* of old Petiver, and the *Musca rarissima* of Ray. We were once nearly drowned in trying to capture it by the side of a muddy stream. The flight of both of these insects, and of all belonging to the genus, is slow and heavy. They seldom fly far, and seem to end their lives near the places where they had their birth,—even to the last "loving the spots which once they gloried in." They are unknown in Britain.[2]

In the genus ASCALAPHUS,[3] Fab. (Plate CCXXX. fig. 19), the antennæ are very long, and terminate somewhat abruptly in a club or expansion. The wings are proportionably broader than those of Myrmeleon. The flight of these insects is rapid and light. They occur chiefly in the warmer parts of Africa and America, although a few are found in Europe. Of these *A. Italicus* occurs in France as far north as the environs of Fontainebleau. We have no very precise knowledge of their transformations. They do not occur in Britain.

SECTION 3D, HEMEROBINI.

The component parts of this group resemble those of the preceding in the general form of the body and wings; but the antennæ are filiform, and the palpi only four in number. They form the old genus *Hemerobius* of Linn. and Fab. which has since been subdivided as follows:—

In HEMEROBIUS proper (of Lat.) the first segment of the thorax is very small, the wings incumbent, and the last article of the palpi is the thickest, ovoid, and pointed.

---

[1] From *μυϱμεξ*, *an ant*, and *λεον*, *a lion*.

[2] *M. formicarium* holds a *nominal* place as a British insect; but we have never felt *assured* of its existence as an indigenous species.

[3] Ασκαλαφος is the ancient mythological name of a bird. We do not know for what reason it was applied to the above genus.

The larvæ are terrestrial, that is, not aquatic. They wander about from place to place, committing great havoc among Aphides, their favourite food,—for which reason they are named *lions des pucerons* by Réaumur. These they seize by means of their horn-like mandibles, and speedily suck to death. Some of the perfect insects are exceedingly beautiful, especially a well-known British species called *Hemerobius perla*, which is of a pale yellowish green, with delicately transparent yet lustrous wings, and brilliant golden eyes. Its flight is feeble. The females lay their eggs on leaves, to the number of twelve or sixteen in a group. They are whitish and oval, and are supported and secured by a long hair-like stalk or pedicle, which some botanists, less versed in edible fungi than Dr Greville, have mistaken for a species of *mushroom!* (See Plate CCXXX. fig. 21.)

Other allied species have the first segment of the thorax large, with the wings usually placed upon the body in a horizontal position. The palpi are filiform, with the last article conical, or almost cylindrical, and frequently shorter than the preceding. The larvæ are aquatic. These insects were placed by Fabricius, along with the species of the genus *Perla* of Geoffroy (from which, however, they differ in the number of articulations of the tarsi), under the genus SEMBLIS, which is itself composed of CORYDALIS, CHAULIODES, and SIALIS, of Latreille.[1]

SECTION 4TH, TERMITINÆ.

This group comprises such Neuroptera as are subject to a semi-metamorphosis, and are active and carnivorous, or rather omnivorous gnawers, in all their states. With the exception of the Mantispæ, which, in regard to their anterior legs, resembling those of the Mantides, are peculiar in their order,—the tarsi have at most four articulations, in which they differ from the preceding genera of the family with which we are still engaged. The mandibles are always corneous and strong.

Some possess tarsi consisting of from five to three articulations, with very distinct and projecting labial palpi. The antennæ are generally composed of more than ten joints, the prothorax is large, in the form of a corselet, and the wings are of equal size, and much reticulated.

In the genus MANTISPA of Illiger (*Rhaphidia*, Scopoli, Linn.; *Mantis*, Fab. Oliv.), all the tarsi have five articulations, and the anterior legs, like those of Mantis, are adapted for prehension. The antennæ are very short and granose, the eyes large, the prothorax very long, thickened anteriorly, and the wings incumbent. This genus consists of not more than five or six species, only one of which, *M. pagana*, is found in Europe. In the genus RAPHIDIA,[2] Linn. Fab. (Plate CCXXX. fig. 24), the tarsi have only four articulations. The wings are incumbent when at rest, the head elongated, and narrowed posteriorly, the thorax long, narrow, and almost cylindrical. The abdomen of the female is terminated by a long exterior oviduct, formed by a couple of laminæ. The species figured on the plate referred to is well known in Britain. It lives in woods. Both the larva and imago feed on other insects. The former is lively in its movements when disturbed. It lives in the fissures of trees, and has the form of a little serpent. In the genus TERMES, which contains the famous white ant (Plate CCXXX. figs. 17, 18, and 23), the tarsi are likewise composed of four joints, but the wings are very long, and are horizontally spread upon the body. The head is rounded, and the thorax almost square or semicircular. The body of these insects is depressed, and the antennæ, at least in the females, are short, and formed like a chaplet. The mouth resembles that of the orthopterous order, and the labium is quadrifid. There are three ocelli, one of which, placed upon the front, is indistinct, and the other two are placed laterally, near the internal margin of the ordinary eyes. The wings are usually rather transparent, colourless, with fine and close-set nervures, but not very distinctly reticulated. There are two small conical biarticulated points at the extremity of the abdomen. The legs are short. A good monograph of this singular and destructive genus is still a desideratum in Entomology. Several species, inhabiting widely distant countries, have been described under the general name of *Termes fatale*, but we have still an insufficient knowledge of their actual and distinguishing characteristics. So confused was the acquaintance of our immediate predecessors with these insects, that the larvæ of *T. flavicolle*, Fab. were placed by Linnæus among his *Aptera*, while the perfect insects formed a part of his genus *Hemerobius*. These Termites are for the most part peculiar to countries placed between or near the tropics. The individuals named neuters or labourers among the white ants (commonly so called) are the wingless larvæ (fig. 17), and in that state their powers of destruction are quite appalling. They live together in assemblages so vast as almost to defy calculation, and excavate galleries under ground, in trees, tables and all kinds of furniture, as well as in the timber of dwelling-houses. Dr M'Murtrie saw a beautiful edifice in the Isle of France that had been abandoned within a few months after its completion, on account of the attacks of these destructive creatures. The whole building was a mere shell.[3] Whatever ligneous bodies are mined by them, retaining little but a superficial bark, soon crumble into dust; and where the roof of a house, or heavy lintel stone, depends on such support, the insecurity may be as easily imagined as described. They sometimes construct external tunnels or covered ways, which conceal them from view while passing to and from their subterranean dwellings. Sometimes their habitations are raised pyramidally above the surface, in other instances they resemble turrets, with an eave-like expansion on the top. Some are broader and extremely solid; and when constructed, as they often are, in groups, they exhibit the appearance of a little village. They are so strongly built, that when raised to only half their height, they are capable of supporting such wild bulls as mount upon them to act as sentinels while the rest of the flock is feeding. When at their full height of ten or twelve feet, they are used by men as stations from which to look across the country, the grass itself being in those regions of equal height. Smeathman, to whom we owe a curious and often-quoted narrative of their history, has frequently stood with four companions on the top of one of their buildings, employing it as a watch-tower by the shore, from which to obtain sight of whatever vessels might heave in sight. Besides the larvæ or workers, we find another set of inhabitants, of which the nature is not yet clearly known, although their functions are obvious. They are known by the name of soldiers or neuters, and were erroneously regarded by Fabricius as the nymphs. They defend the habitation. When a breach is effected with a pick-axe, they make their appearance, and snap about in all directions with their mandibles,—apparently in a state of considerable indignation. When the attack has ceased, the soldiers retire, and are succeeded by the labourers, who speedily repair the breach. They are still attended, however, by a few soldiers, who seem to act as superintendents of the work. The nymphs bear the rudiments of wings; in other respects they resemble the larvæ. No sooner do they become perfect, by acquiring the organs of flight, than they wing their way from their original dwellings, during the evening, or the stillness of night, and in incalculable numbers. At sunrise, however, by a singular law of nature, they lose their wings, which dry up, become shrivelled, and fall to the ground. In this defenceless state they become the prey of many reptiles, and of insect-eating birds. Indeed they seem not to be despised in that respect even by man himself; for not only are they greedily devoured by Hottentots and negroes, but have been often eaten by Europeans with delight. Mr Smeathman found them " delicate, nourishing, and wholesome, without sauce or other help from cookery, than merely roasting them in the manner of coffee." He indeed discoursed with various friends on the taste of white ants, and on comparing notes, they agreed that these insects were " delicious and delicate eating." One gentleman compared them to sugared marrow, while another thought they tasted like " sugared cream and a paste of sweet almonds."[1] Although prodigious numbers perish in consequence of this migratory instinct, such are their vast powers of fecundity, that old colonies are soon replenished, or new ones formed. According to Smeathman, the provident larvæ seize upon all the winged couples they can find, and shut them up in a roomy cell or nuptial chamber, where they supply them with abundant food; " mais j'ai lieu de présumer," says Latreille, " que l'accouplement a lieu, comme celui des fourmis, dans l'air ou hors de l'habitation, et que les femelles occupent seules l'attention des larves, dans le but de former une nouvelle colonie." The abdomen of the pregnant female (Plate CCXXX. fig. 23) becomes so greatly dilated as to exceed the rest of her body by 1500 or 2000 times, and she is then about a thousand times heavier than her husband. Indeed well she may, if, as is reported, she is endowed with the power of laying *thirty-one million five hundred and thirty-six thousand* eggs in the course of a year. Those fond of arithmetic may try to discover how many grandchildren she is likely to possess by the termination of the ensuing season.

[2] From ῥαφις ιδος, *a needle*.

[3] Cuvier's *Animal Kingdom*, American edition, vol. iv. p. 73.

Certain Termites (*T. arborum*) live on trees, where they build nests as large as sugar casks, and from seventy to eighty feet above the ground. These are formed of particles of gnawed wood cemented by a gluten either secreted by themselves, as silk is by caterpillars, or gathered from gummiferous trees. They are so strongly attached to their supporting branches as to resist the violence even of those tornadoes which so often in tropical countries level alike the palaces of kings, and " huts where poor men lie." Indeed they cannot be detached except by being hewn in pieces. The genus Termes is not unknown in Europe. *T. lucifugum* of Rossi (*Faun. Etrusc.*) occurs in the southern provinces of France, where it dwells in the interior of various trees. It has so greatly multiplied in the workshops and storehouses of the navy-yard of Rochefort that it cannot be extirpated, and is the cause of constant damage. *T. flavicolle* proves extremely injurious to the olive trees in Spain. Our " favoured isle" is fortunately free from these and many other continental pests,—if an entomologist may so express himself regarding species which would no doubt be highly prized *as British* by many a fond collector.

The remaining Termitinæ are characterized by their biarticulate tarsi, and their short and indistinct labial palpi. The antennæ consist of about ten joints; the anterior segment of the thorax is very small; and the inferior wings are less than the superior. They form the genus Psocus of Latreille, which consists of very small species with short soft bodies, often hunched or inflated, with a large head, setaceous antennæ, projecting maxillary palpi, and incumbent wings, slightly reticulated or but simply veined. These are active insects, living beneath the bark of trees, in wood, straw, &c. Some occur among books and in collections of plants and insects. They seem peculiar to Europe. *P. pulsatorius* derives its name from the sound, resembling the ticking of a watch, which, in common with some other insects, it utters in our apartments. Its anatomy is described by Germar.[2] We have many British species.

SECTION 5TH, PERLIDES.

Of these the tarsi are furnished with three articulations, and the mandibles are almost always partly membranous and small, with the inferior wings wider than the superior, and doubled on themselves at their inner edge. The genera are PERLA of Geoffroy, and NEMOURA[3] of Latreille (*Phryganea*, Linn.).[4]

FAMILY III.—PLICIPENNES.

The insects of this family have no perceptible mandibles. Their inferior wings are usually broader than the upper ones, and longitudinally plaited. They compose the genus PHRYGANEA[5] of Linn. divided by Latreille into SERICOSTOMA[6] and PHRYGANEA proper (see Plate CCXXX. fig. 26). In the larva state (figs. 22 and 25) they live in tubes or cases of their own construction, made of a great variety of substances, according to the species. Latreille regards them as simply herbivorous, although other authors maintain that, in addition to aquatic plants, they prey upon the larvæ of gnats and dragon-flies.

We shall conclude our sketch of this order by observing that the characters and habits of the genus PHRYGANEA being very peculiar, the species have in recent times been separated from the neuropterous tribes, and erected into an additional order, TRICHOPTERA, Kirby, so called from ϑϱιξ, τϱιχος, *hair*, in allusion to the usual roughness of the wings. Both Réaumur and Degeer had previously observed that they were allied to the lepidopterous order. " Although some other insects," Mr Kirby has remarked, " (*Myrmeleon* and *Hemerobius*), placed in the *Neuroptera*, do not agree with the rest in their metamorphosis, yet in their perfect state they exhibit the principal characters of the order, and therefore are properly retained in it; but *Phryganea* differs from the rest both in metamorphosis and characters. Its metamorphosis is very peculiar, the larva imitating many of the *Tineæ*, in constructing, of various materials, a kind of case for its habitation, from which circumstance they are commonly called *case-worms;* and the pupa, which is *incomplete*, and at first quiescent, just before its final change, by a wonderful provision of an all-wise Creator, becomes locomotive, that it may place itself in a situation of security out of the water before it casts its exuviæ; and for this purpose the antennæ and the four anterior legs are not confined under the general envelope, though each has its peculiar integument, so that the animal can use them when the time comes for it to emerge from the water, and commence a denizen of the air. The imago exhibits few or none of the characters of the other *neuropterous* genera. The wings are veined in a peculiar manner, without reticulations, in some degree like those of *Lepidoptera*. The antennæ resemble much those of the Tinea tribe, and the tibiæ of many of them are armed with the two pair of spurs observable in so many of the moths; but they have no spiral tongue, the wings, though hairy, have no scales, the under wings are folded longitudinally, and the head, besides the usual compound eyes, has three stemmata. If these remarks appear to entomologists well founded, and it be thought right to consider *Phryganea* as constituting a new order, I think it might be distinguished, since the names of all the known species are hairy, by the name of *Trichoptera*."[1]

ORDER V.—HYMENOPTERA.[2]

This order, of more direct utility to man than many others, in as far as it contains the species which yield us wax and honey, is characterized, like the preceding one, by the possession of four membranous and naked wings. The mouth consists of mandibles, maxillæ, and an under and an upper lip. The organs of flight, however, differ from those of the Neuroptera, in being simply veined rather than reticulated; and the upper wings are always somewhat larger than the under pair. The abdomen of the female is terminated either by an ovipositor or sting. Besides the ordinary visual organs, these insects are all provided with three small stemmatic eyes. The antennæ are variable, not only in different genera, but in different sexes of the same species. In the majority, however, they are filiform or setaceous. The maxillæ and the labium are generally long and narrow, fixed in a deep cavity of the head by lengthened muscles, semi-tubular at their lower portion, often folded at their extremity, and serving rather for the transmission of nutritive juices than for mastication properly so called. Indeed in several these parts unite to form a kind of trunk or sucker. The ligula is membranous, whether widened at the extremity, or long and filiform, with the pharynx at its anterior base, and frequently covered by a kind of sub-labrum or epipharynx. The palpi are four in number, two labial and two maxillary. The thorax as usual consists of three segments, of which the foremost is very short, and the two remainder are intimately united. The wings cross each other horizontally over the body, and the upper pair have a little rounded convex knob at their base. The abdomen is composed of from five to nine segments, the number being frequently six in the females and seven in the males. It is usually suspended, as it were, to the thorax by a small and slender pedicle; in which case its second articulation seems to be the first, the latter being in fact confounded with the metathorax. The ovipositor and the sting (both being constructed on the same model) are composed, in the generality, of three long and slender pieces, two of which serve as a sheath for the third, which is itself, when under the form of a sting, composed of a pair of pieces joined in one. The tarsi are composed of five articulations, none of which is divided.

The structure of the wings of Hymenoptera has served as the basis of a noted method for their classification, made known by M. Jurine.[3] This method is founded on the nature and number of the nervures of the wings, and of the cells or intermediate diaphanous spaces formed by their ramification. The nature of our present treatise, which we have already extended to the proposed limits (and we are still far from our conclusion), will not, however, admit of our entering fully into such details.[4]

The digestive system of Hymenoptera consists in general of two stomachs, of which the second is elongated; of a short intestine, terminated by a widened cloaca; and of numerous biliary vessels, inserted near the pylorus. In regard to their tracheal apparatus, M. Leon Dufour has remarked, that all the Hymenoptera which he has examined exhibit a greater degree of perfection in that part of their structure than any other order of insects. Instead of being composed of cylindrical and elastic vessels, of which the diameter decreases by successive divarications, they present constant dilatations, or determinate vesicles, favourable to the greater or less continuance of air, and capable of being distended or otherwise, accord-

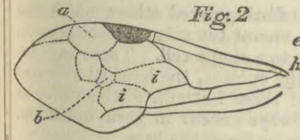

Fig. 2

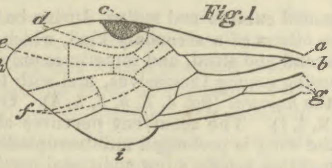

Fig. 1

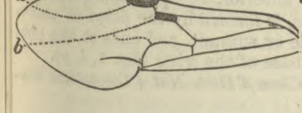

Fig. 3

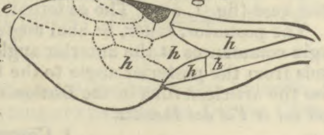

Fig. 4

[4] When we examine a hymenopterous insect with a glass, or even by means of the unaided sight, we shall observe that the external or anterior margin of the upper wings presents two strong approximate parallel nervures, deriving their origin from the thorax, and united by means of a strong expansion of the membrane of the wing. The external nervure is called the *radius*, fig. 1, *a*; the internal the cubitus, fig. 1, *b*. Each of these terminates in a dark-coloured expansion called the stigma, fig. 1, *c*. Besides these larger nervures, which some call *primitive*, several others spring likewise from the base of the wing, and are named *brachial*, fig. 1, *g*. All these principal branches give rise to shorter intersecting nervures, the interlacement of which partitions the wing as it were into membranaceous departments, designated by the name of cells. Several of these, by reason of their constancy of disposition in each genus of hymenopterous insects, have been used with advantage by Jurine for the purposes of classification. A nervure, called the *radial* (fig. 3, *a*), usually springs from the middle of the stigma, and attaining the tip or anterior angle of the wing, leaves between itself and the anterior margin a membranous space, known as the *radial cell* (fig. 4, *a*). If there should, moreover, spring from the stigma a lesser nervure, dividing the cell into two parts, we recognise a pair of radial cells. In this case, however, the larger nervure does not derive its origin from the central line of the stigma, but farther back, or from its basal portion (fig. 1, *d*). It sometimes also happens that the radial nervure, proceeding from the stigma, encounters, before it gains the margin of the wing, a small intersecting nervure, itself proceeding from that margin. The radial cell is then said to be appendaged (*appendicée*), fig. 2, *a*.

Another range of cells, of some importance, has received the name of *cubital* (fig. 1, *e*). It is formed by the posterior edge of the radial nervure, and by another nervure named the *cubital*, which springs from the extremity of the cubitus, near the stigma, and ing to the quantity of their contents. On each side of the base of the abdomen there is a large oval vesicle of the kind alluded to, of a dull milky white, giving rise here and there to radiating bundles of vascular tracheæ, which distribute themselves to the neighbouring organs. On entering the thorax it becomes restricted, is again dilated, and ends insensibly in a tube, of which the subdivisions are lost in the head. Behind these two abdominal vesicles the respiratory organ is prolonged in the shape of two filiform tubes, which give off an infinity of little air-bearing branches, and become confluent towards the anal extremity.[1]

Hymenopterous insects undergo a complete metamorphosis. Most of the larvæ resemble little worms, unprovided with feet. At least those of the second and following families answer that description. Those of the first family, however, have six feet, furnished with hooks; and besides these they frequently possess from twelve to sixteen others of a simply membranous texture. These latter larvæ are named by the French *fausses chenilles.* Both kinds are provided with a scaly head, with mandibles, maxillæ, and a labium, at the extremity of which is a *spinner* for the passage of that silky substance which is ere long employed in the construction of the nymph's cocoon. Some live on vegetable substances; others, and these are the footless or apodal kinds, feed on insects, with which they are supplied by the provident attention of their mothers, which either carry food to their admirably constructed dwellings, or, as among the Ichneumonides, deposit their eggs at once on living larvæ, of which the excluded young soon become the tenacious and destructive parasites. Among bees a vast number of individuals of ambiguous or undeveloped sex are charged, among other arduous labours, with the sustenance of the helpless young, a task performed with a propriety and precision which, with their many additional attributes of instinctive skill, render their proceedings worthy to be classed, if not as standing miracles of nature, at least as deserving the careful contemplation of the wisest minds.

> Happy if full of days—but happier far,
> If, ere we yet discern life's evening star,
> Sick of the service of a world that feeds
> Its patient drudges with dry chaff and weeds,
> We can escape from custom's idiot sway,
> To serve the sovereign we were born to obey.
> More sweet to muse upon his skill display'd
> (Infinite skill) in all that he has made!
> To trace, in nature's most minute design,
> The signature and stamp of power divine,
> Contrivance intricate, express'd with ease,
> Where unassisted sight no beauty sees,
> The shapely limb, the lubricated joint
> Within the small dimensions of a point,
> Muscle and nerve miraculously spun,
> His mighty work, who speaks—and it is done,
> The Invisible in things scarce seen reveal'd,
> To whom an atom is an ample field:
> To wonder at a thousand insect forms,
> These hatch'd, and those resuscitated worms,
> New life ordain'd and brighter scenes to share,
> Once prone on earth, now buoyant upon air,
> Whose shape would make them, had they bulk and size,
> More hideous foes than fancy can devise;
> With helmet heads and dragon scales adorn'd,
> The mighty myriads, now securely scorn'd,
> Would mock the majesty of man's high birth,
> Despise his bulwarks, and unpeople earth.[2]

In the winged or perfect state, hymenopterous insects generally occur on flowers, and they may be regarded as more abundant in southern than in northern regions. We shall not here dilate upon the generalities of the order, as it is our intention to notice all the more remarkable historical facts, in our sketch of the principal tribes and genera. We shall merely remark, that notwithstanding the numerous and always delightful observations of Réaumur, Degeer, Huber, Latreille, Walkenaer, and others, the hymenopterous order still presents a vast and fruitful field of discovery to the zealous cultivator of entomological science. Christus has combined in a special work[3] a great deal of excellent information; but his labours are imperfect in relation to the present condition of the subject. The *Systema Piezatorum* of Fabricius is merely a descriptive catalogue of species, assembled together without any precise notion of sexual distinctions, not seldom inaccurate in the exposition of generic characters, and extremely incomplete in relation to the European species. Jurine has carefully distinguished the sexes, and his groups are an improvement on those of his predecessors. Lepelletier de St-Fargeau,[4] Serville, Klug,[5] and, last though not least,

---

directs itself towards the tip of the wing (fig. 3, *b*). This range is frequently divided into two, three, or four lesser cells, by means of intersecting nervures (fig. 4, *e*, and fig. 1, *e*). If two of these cells are much developed, and the second one, on the contrary, is so circumscribed that it cannot reach the margin of the radial nervure, we have then a peculiar character. The two developed cells, instead of being separated from each other by the entire interval of the second cell, are kept apart, for a space, only by a simple nervure, the length of which is proportional to the curtailment of the second cell; and in this way the latter has no other connection with the radial cell above it, than that it adheres to, or depends from it, as it were, by a kind of pedicle or stalk,—for which reason it is then named *petiolated* by Jurine (fig. 2, *b*). If it happens that the cubital nervure does not attain to the extreme margin of the wing, the spaces which it partly forms are regarded as *incomplete.*

It has been already stated that, besides the large nervures named cubitus and radius, Jurine has distinguished others, which also spring from the base of the wing, as at fig. 1, *g*. These produce others of a secondary kind, which mount towards the cubital cells, sometimes attaining to the first and second, sometimes to the second and third, and sometimes only to a single cell. These have received the name of recurrent nervures (fig. 1, *f*). By anastomosing among themselves, and with the cubitus, the brachial nervures and their branches form several cells, which Jurine has named the *humeral* (fig. 4, *h*, *h*, *h*, *h*, *h*). Of these Latreille distinguishes as *discoidal*, such as are situated in the centre of the wing (fig. 2, *i*, *i*). The recurrent nervures always concur in their formation. Among lepidopterous insects, the cell situated in the centre of the wing is prolonged uninterruptedly as far as the base.

Since we have entered into these details, we may here also mention briefly a few additional particulars, relating chiefly to the nomenclature of the outline of the wings. The *base* is that part which articulates with the thorax (fig. 1, *a*, *b*, *g*). The *point*, *summit*, or *anterior angle*, is that part which is most directly opposed to the base (fig. 1, *h*). The external, anterior, or upper margin of the wing extends from the base to the summit (fig. 1, *a*, *c*, *d*, *e*, *h*). The posterior, inner, or anal angle, is formed by the point of union of the posterior and inner margins (fig. 1, *i*). The posterior margin commences at the anterior angle or summit, and ends at the posterior or inner angle (fig. 1, *h*, *f*, *i*). The internal margin extends from the posterior angle to the base of the wing (fig. 1, *i*, *g*).

Hymenoptera Terebrantia.

our own inestimable Kirby,[1] have published valuable though partial additions to our knowledge of the history and classification of the hymenopterous tribes.[2]

Latreille divides our present order into two primary sections.

TEREBRANTIA,[3]

In which the Females are provided with an Ovipositor.

FAMILY I.—SECURIFERA.[4]

Abdomen sessile, or united by the entire breadth of its base to the thorax, of which it appears a continuation, without distinct or separate power of movement. The females have an ovipositor (*tarière*), generally in the form of a saw, and which serves not merely for the deposition of the eggs, but also for the construction of a proper place for their reception. The larvæ have always six scaly feet, and frequently several others which are membranous. This family forms two tribes.

Tribe 1st, Tenthredinetæ, or Saw-flies.

Of these the mandibles are lengthened and compressed. The ligula is divided into three, as if digitated. The ovipositor is composed of two plates, toothed like a saw, pointed, united, and lodged in a groove of the posterior extremity. The maxillary palpi are always composed of six articulations, and the labial of four. The latter are always the shorter. Both pairs of wings are divided into numerous cells. This tribe corresponds to the great genus Tenthredo of Linnæus.

The abdomen of these insects is cylindrical, rounded posteriorly, composed of nine segments, and so united to the thorax as to appear almost like a uniform continuation of that part. The wings appear as if rumpled, and there are two little grain-like coloured bodies behind the scutellum. The form and composition of the antennæ vary. The mandibles are strong and toothed. The extremity of the maxillæ is almost membranous, or at least of a less coriaceous consistence than the base. The palpi are filiform, or nearly setaceous, and composed of six articulations. The ligula is straight, rounded, divided into three parts, of which the central is the narrowest; its sheath is usually short. The abdomen of the female is provided at its lower extremity with a double moveable ovipositor, scaly, serrated, pointed, and enclosed within two other concave plates, which serve it as a sheath. It is by the action of the teeth of this instrument that the insect perforates the stalks and other parts of plants, in which she lays her eggs. These she afterwards imbues with a peculiar frothy liquor, which seems to prevent the parts of the plant from reuniting, and even causes the formation of a concave chamber, or of ligneous parts resembling galls, in which the excluded larvæ dwell, either in a state of solitude, or in company, according to their kind. After undergoing its final metamorphosis, the perfect insect makes its escape by gnawing a circular overture. The larvæ of many species, however, live exposed upon the foliage of trees and plants. They bear a great resemblance to caterpillars in their general form and colouring, but they present either from eighteen to twenty-two feet, or only six; whereas in caterpillars properly so called, these parts range merely from ten to sixteen. They frequently continue in the larva state for several months, or throughout the winter, and remain but a short time in the nympha state, previous to the assumption of which they spin a cocoon. We shall briefly notice the principal genera into which these insects are now divided.[5]

In Cimbex of Olivier and Fab. (Plate CCXXXI. fig. 1) the antennæ are alike in both sexes, and terminate in a button-like expansion. The larvæ have twenty-four feet, and some of them when tormented will spout out a greenish liquid to the distance of a foot. In Hylotoma, Lat. (ibid. fig. 2), the antennæ exhibit only three distinct articulations, of which the last is in the form of an elongated prismatic or cylindrical club, more slender, ciliated, and sometimes forked in the males. A well-known species (figured as above), the *Tenthredo rosæ* of Linn. belongs to this genus. In the genus Tenthredo properly so called (ibid. fig. 3), the antennæ are composed of nine articulations, which are simple in both sexes. The larvæ have from eighteen to twenty-two feet. In the perfect insects the number of teeth of the mandibles varies from two to four. The amount of radial and cubital cells of the wings also varies in different species. Hence the formation of the genera *Allantus*, *Dolerus*, *Nematus*, &c. by Jurine, Leach, and other naturalists. The genus Cladius of Klug has also nine joints in the antennæ, but those parts are pectinated on one side in the males. In Athalia of Leach the body is short and thick, as in Hylotoma, but the antennæ, simple in both sexes, have from ten to fourteen articulations. The genus *Pterygophorus* of Klug are remarkable for their antennæ, composed at least of sixteen articulations, being pectinated or fan-shaped in the males, and serrated in the females. In Lophyrus of Lat. (Plate CCXXXI. fig. 4) the antennæ are doubly pectinated in the males, and resemble a triangular plume (fig. 5); they are shortly serrated in the females (fig. 6).[6] In all the preceding genera the labrum is quite apparent, and the four posterior tibiæ are either unfurnished on their inner side with spines, or exhibit only one. But in the following the labrum is concealed, or but slightly projecting, and the inner side of the four posterior tibiæ exhibits before its extremity two, and frequently three spines. Such are Megalodontes, Lat. in which the antennæ are serrated or pectinated, and Pamphilus of the same author, in which those organs are simple in both sexes.

The concluding Tenthredinetæ have the ovipositor prolonged beyond the groove, and projecting posteriorly. The antennæ are simple, and always composed of a great number of articulations. They constitute the genera Xyela, Dalm., Cephas, and Xiphydria, Lat. Of the last named the antennæ are inserted near the mouth, and become attenuated towards the termination (Plate CCXXXI. fig. 7).

[6] *Lophyrus pini*, the species figured on the plate referred to, has become much more common of late years in Scotland, since the plantation and growth of larch forests.

Hymenoptera Terebrantia.

TRIBE 2D, UROCERATA.[1]

The insects of this tribe are distinguished from those of the preceding by their mandibles, which are short and thick, by their ligula, which is entire, and by the ovipositor of the female, which is sometimes projecting and composed of three thread-like parts, sometimes spirally rolled within the abdomen, and of a capillary form. They compose the old genus SIREX of Linn.

The antennæ of these insects are filiform or setaceous, vibratory, and composed of from ten to twenty-five articulations. The head is rounded and nearly globular, the labrum very small, the maxillary palpi filiform, consisting of from three to five articulations, and the labial of three, of which the last is largest. The body is almost cylindrical. The anterior or posterior tarsi, and in several species the colour of the abdomen, differ according to the sexes. The females deposit their eggs in ancient trees, generally in those of the pine tribe. The ovipositor is lodged at the base of the abdomen, between two valves, which form a protecting groove.

In the genus ORYSSUS, Lat. (Plate CCXXXI. fig. 9), the antennæ are inserted near the mouth, the mandibles are without teeth, the maxillary palpi are long and five-articulate, the posterior extremity of the body is almost rounded and slightly prolonged, and the ovipositor is capillary and spirally rolled in the interior of the abdomen. There are only two species found in Europe, both of which are exceedingly active, and occur on trees in spring. We have figured *O. coronatus*, the sole British species. In SIREX properly so called (*Urocerus*, Geoff.), Plate CCXXXI. fig. 8, the antennæ, inserted near the front, consist of from thirteen to twenty-five articulations, the mandibles are toothed on their inner side, the maxillary palpi are very small, almost conical, of two articulations, and the extremity of the last segment of the abdomen is prolonged in the form of a tail. The ovipositor consists of three threads. These insects are of rather large size. They inhabit more particularly forests of pine and fir, in cold and mountainous countries, and during flight produce a buzzing noise, like that of an humble-bee. The larvæ have six feet, with the posterior extremity of the body terminating in a point. It lives in the interior of wood, where it spins a cocoon, and undergoes its metamorphosis. Our most noted species is the *S. gigas* of Linn. The male has a yellow abdomen, with a black extremity; the female is black, with a yellow spot behind each eye, and the second and three terminal rings of the abdomen also of the latter colour. Owing to the disparity of aspect of the sexes, they have been not unfrequently described by naturalists as distinct species.

FAMILY II.—PUPIVORA.[2]

The various groups which compose this family are distinguished by the abdomen being attached to the thorax by a simple portion of its transverse diameter, or even in many instances merely by a slender thread or pedicle, so that its mode of insertion is distinct and obvious, and admits of a separate movement. The larvæ are apodal, and for the most part parasitical and carnivorous. Latreille divides them into six tribes, as follows.

TRIBE 1ST, EVANIALES.

In these the wings are raised, and the upper at least are areolated. The antennæ are filiform or setaceous, and composed of from thirteen to fourteen articulations. The mandibles are dentated on the inner side. The maxillary palpi consist of six, and the labial of four articulations. The abdomen is implanted on the thorax,—in some, just beneath the scutellum. The ovipositor is usually projecting, and composed of three setæ.

The following are the principal genera: EVANIA, Fab. (*Sphex*, Linn.) Plate CCXXXI. figs. 10 and 13; PELECINUS, Lat., ibid. fig. 12; FÆNUS, Fab. (*Ichneumon*, Linn.) ibid. fig. 14; AULACUS, Jur. and PAXYLLOMA, Brébisson.

TRIBE 2D, ICHNEUMONIDES.

In these the wings are also veined, and the superior always exhibit on their disc closed or completed cells. The abdomen takes its rise between the two posterior legs. The antennæ are generally filiform or setaceous (very rarely clubbed), and composed of a great number of articulations. In the majority the mandibles have no tooth on the inner side, and terminate in a bifid point. The maxillary palpi, always apparent or projecting, have usually not more than five articulations. The ovipositor consists of three threads or setæ.

Such is a brief exposition of the technical characters of a tribe of insects which embraces almost the whole of the great genus ICHNEUMON of Linnæus, and of which the natural economy and habits are so remarkable that we shall here take leave to extend our observations on their history. Perhaps we could not better illustrate the complex nature of the modern science of Entomology than by stating, that what we must here pass over in the space of a few columns, and which, even in the publications of comparatively recent writers, does not form a very important or greatly enlarged feature, occupies, in a work to which we have lately devoted our attention, upwards of 2800 pages.[3]

The general term Ichneumonides comprehends an extensive series of insects, important on account of the purposes to which they are subservient in the economy of nature, and deriving considerable interest from the peculiar manner in which these purposes are effected. They differ from most of the other members of the class to which they belong, in their mode of providing for their young,—presenting this peculiarity, that they deposit their eggs in the living bodies of other insects. In a tribe of such extent, considerable variety of external appearance necessarily prevails; but a genuine Ichneumon may in general be known by its elongated form, attenuated, and in most cases petiolated abdomen, terminated frequently in a long fissile seta; and by its filiform, porrected, often recurved and annulated antennæ, to which a constant vibratory motion is imparted. The European species vary in size from a fraction of a line to fifteen lines; those of tropical countries, however, greatly exceed these dimensions, a few of them ranking even among the largest insects. Upwards of 1300 species have been described as natives of Europe, of which number a great many hundreds exist in Britain.[4] The frequency of their occurrence, and singular habits of life, which often force them unexpectedly on the notice of naturalists while engaged in the study of insect transformations, have secured some degree of attention for this tribe, even from the earliest periods. The word Ichneumon occurs in the natural history of Aristotle, by whom it is applied to a species of Sphex. Ray appears to be the first who used it to designate the tribe of insects to which it has ever since been restricted. Little, however, was known regarding the structure or habits of these creatures till the time of Frisch, who subjected them to an anatomical examination, and described the parts of the mouth, and formation of the wings, with great accuracy and minuteness. He was the first who employed the form and relative position of the cells of the latter to assist in distinguishing genera. Much valuable information resulted from the observations and experiments of Réaumur, whose work may be referred to for many interesting details regarding the manners and habits of the Ichneumonides.[1] Degeer also contributed materially to elucidate their history, and proposed a new arrangement of the family, characterized by his usual accuracy of discrimination.

---

[1] From ουρα, *tail*, and κερας, *horn*.

[2] From *pupa*, and *voro*, to devour, in allusion to their destruction of other insects by depositing eggs in their bodies, which usually destroy the pupæ.

[3] We allude to the complete and careful *Ichneumonologia Europæa* of Professor Gravenhorst of Breslau, in three very thick volumes 8vo, 1829.

[4] In the *Systema Naturæ* (12th edition), Linnæus describes only seventy-seven species of Ichneumon.

In the numerous works on Entomology which appeared during the latter half of the eighteenth century, our knowledge of these insects kept pace with the increased zeal manifested towards the study of natural history during that important period. Linnæus, Scopoli, Fabricius, Schrank, Panzer, and others of inferior name, applied themselves successfully to investigate their history—reducing the information derived from their predecessors to a more systematic form, and greatly increasing the amount of known species. In 1807 Jurine published his new method for the classification of Hymenoptera, already mentioned. The application of his principles to the Ichneumonides afforded less satisfactory results than in most of the other tribes. Like all systems founded on a partial view of organic structure, it led, in many instances, to the violation of natural order, by separating cognate species, and associating others having no positive affinity. But though Jurine failed to establish an efficient mode of arrangement, he rendered important service to subsequent inquirers, by describing minutely, and furnishing with a suitable terminology, the variously modified forms of the organs of flight, which are found to afford characters of considerable value for the discrimination of genera. Latreille at different times published arrangements of this tribe, and by the number of his sectional divisions, generally founded on obvious characters, greatly facilitated the identifying of species.[2] But the amount of these had increased to such an extent, and they were found to approximate so closely to each other in external characters, that a comprehensive division, and a more detailed description of specific difference, became indispensable. This desideratum has recently been supplied by the publication of an extensive and elaborate work on the Ichneumonides by Professor Gravenhorst; an individual eminently qualified to unravel the complexities of this difficult tribe. An extensive intercourse with men of science enabled him to amass a large collection of these insects from all parts of Europe; while habits of minute observation and patient research, combined with just views of systematic arrangement, and an accurate perception of the affinities of consecutive groups, qualified him to employ to the best advantage the ample materials thus obtained. The result of his labours appeared in 1829, as specified in a note on our preceding page. The arrangement adopted is fundamentally the same as that previously published by himself and Nees ab Esenbeck.[3]

Hymenoptera
Terebrantia.

The body of the Ichneumons is more or less elongated, and in most instances naked and shining, seldom rough or impressed with punctures. It is occasionally covered, particularly on the head and thorax, with a pubescence composed of slender erect hairs, or it is somewhat sericeous and opaque, with a soft decumbent pubescence. The prevailing colours are rufous, black, and yellow, variously intermingled with lines and patches of white. In the great majority of species, there are one or two spots of the latter colour on the thorax, at the insertion of the wings. The scutellum is most frequently white. The feet are very often of a reddish colour, at times red and black; but they are never entirely black, the anterior femora being always pale on the under side. The head is prominent, generally orbiculate or subovate anteriorly, in many instances a little narrowed towards the neck, and nearly of the same breadth as the thorax. The forehead is sometimes armed with one or two short erect horns, placed between the antennæ and stemmata. The latter are three in number, and disposed in a triangular form. The antennæ in the greater number of species are shorter than the body; in a few they are of the same length, very rarely longer, porrected, generally curved or involuted after death, especially in the females, filiform or setaceous, sometimes slightly compressed at the middle, as in some species of *Phygadeuon*, distinctly compressed in the *Barycerotes*, much compressed and dilated in the *Eucerotes*, and clavate in the *Hellwigiæ*. They consist of from eighteen to sixty articulations, of which the first or radicle is small, globose, and sunk in the head; the second or scape sub-cylindrical or sub-clavate, rarely ovate, very rarely sub-globose, always thicker than the rest (except in the antennæ of the *Barycerotes* and the *Eucerotes*), and longer than the two following; the third and fourth very short, rather stout, and often so closely united that they may be regarded as one joint; the fourth always shorter than the third, which is at times very inconspicuous; the fifth long, cylindrical; the remainder gradually decreasing in length, so that the apical joints often appear transverse. Such is the general appearance of the antennæ; but they are liable to numerous modifications. The mandibles are corneous, more or less arcuate, generally broadest at the base, and narrowed towards the apex; in a few instances they are straight, and in others linear, or even dilated at the extremity, where they are furnished with two teeth, except in a very few species, which have the apex entire or tridentate. The maxillæ consist of two parts, of which the basal portion, or stipes as it has been called, is usually of a corneous consistence and somewhat lanceolate form; the other portion (mala) is of a membranaceous substance, and bifid or bipartite. The palpi are four in number, elongate, filiform, and unequal; the maxillary are rather long, and consist of five joints, very rarely of four. They have been described by Fabricius and Panzer as having six joints. The third joint is generally the longest; the first, second, and fourth, very short; sometimes, however, one or other of these, or the fifth, is longest, and in a very few cases the third is shortest; in some species all the articulations are of equal length. The labial palpi are rather short, and consist of five joints, very rarely of three.

The Ichneumonides, like the rest of the Hymenoptera, are provided with four wings, composed of thin membrane, and of corneous ribs. These ribs are generally denominated nerves or nervures; and the various spaces into which the wing is divided by their intersection are called

---

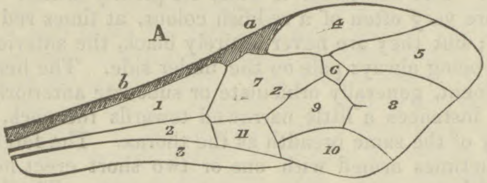
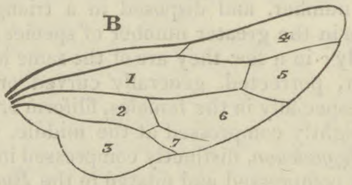
[2] *Histoire Naturelle, générale et particulière, des Crustacés et des Insectes*, tom. iii. et xiii.; see also *Règne Animal*, t. v. p. 281.

[3] The arrangement alluded to appeared in 1818, in the 9th volume of *Novorum Actorum Academiæ Naturæ Curiosorum.*

Hymenoptera Terebrantia.

cells or areolets. The base of the wing (*radix*), or that portion of it which is inserted into the thorax, is of a substance intermediate between corneous and membranaceous, and is always more or less coloured. It is partially covered with a hard convex scale (*squamula*), which, however, may more properly be regarded as an appendage of the thorax. The anterior wings (fig. A) are longer than the posterior, narrow throughout a considerable portion of their length, and gradually dilated towards the extremity. The *stigma* (*a*) is distinctly marked, and varies much in size. The thick rib of the anterior margin, extending between the stigma and the dorsal angle of the wing, is called the *radius* (*b*). By the anastomosing of the nerves, ten or eleven cells are formed, of which the three at the base of the wing are named humeral (*humerales*), 1, 2, 3; one radial (*radialis*), 4; two or three cubital (*cubitales*), 5, 6, 7; two lying under these discoidal (*discoidales*), 8, 9; and two towards the margin posterior (*posticæ*), 10, 11. When the cells are viewed in relation to the breadth of the wing, the three situate at the apex or posterior margin are said to be external (5, 8, 10); those next the humeral cells internal (7, 11); and those between the external and internal cells intermediate (6, 9). Of the humeral cells, that which lies next the radius is named the external (1), that next the margin the internal (3), and that which lies between these two the intermediate (2). The intermediate cubital cell (6) is generally denominated the areolet, and is important on account of the distinctive characters it affords. The interior cubital cell (7) is very large, in consequence of the nerve which ought to divide it into two parts, at least which does so in the other Hymenoptera, having become obsolete. In many species, however, a portion of this nerve is visible (*z*); and in some instances it extends nearly to the centre of the cell; but it is usually very short, or a projecting angle alone indicates the point whence it ought to issue; and in the less typical species all traces of it are obliterated. The areolet likewise is occasionally awanting; different individuals of the same species have it or have it not; and examples occur in which it is distinctly formed in one wing and awanting in the other. In general, however, it is present, and may readily be distinguished from the other cells by its inferior size and angular form. It is either five-angled or quadrangular, triangular or orbiculate. But all these forms are liable to numerous modifications, and one passes into another. The posterior wings (B) are shorter and narrower than the anterior, and nearly of equal breadth throughout. By the anastomosing of the nerves, seven cells are formed, of which the three at the base of the wing are named internal (1, 2, 3), and four at the posterior margin external (4, 5, 6, 7). In the sub-genus *Pezomachus* the wings are generally absent, and when present are extremely imperfect, and usually unfit for the purposes of flight, although their structure, as far as it can be traced, exactly corresponds to that of the more perfect species. The abdomen, which is very variable in form, is composed of seven or eight segments, the eighth being more or less concealed, and often entirely obsolete. This imperfect development of some of the segments has led authors to give various accounts of their number. In addition to the seven usually enumerated, Audouin is of opinion that there is another of very small size, which unites the abdomen to the thorax. According to Blainville, there are never fewer than ten segments, of which the two at the apex are always concealed. The first or basal segment bears on each side of it a small tubercle, more or less distinct, which forms the outlet to a spiracle. When the tubercles are placed very near the base, and the anterior part of the basal segment is not much narrower than the following segments, and these nearly correspond to the breadth of the thorax, the abdomen is said to be sessile; the posterior part of the first segment being so short that it can with difficulty be distinguished, and the anterior part consequently appearing to adhere immediately to the thorax. If this segment, or the posterior part of it, be gradually contracted towards the base, the abdomen is said to be sub-sessile or sub-petiolate. When the posterior part is narrow and elongated, linear or filiform, that part is called the petiole or footstalk, and the abdomen is said to be petiolate.





The sexes of these insects can with difficulty be distinguished,—few species affording any permanent external marks of sexual difference. The males in some instances differ from the females in having a more slender abdomen, in others the antennæ are thicker, and in some species they are more slender than in the females. Many of the latter are distinguished by having a white ring round the antennæ,[1] which after death become curved or spirally convoluted. The males may frequently be known by having the colours with which they are adorned clearer and more distinctly defined than in the opposite sex. But the most certain, and often the most obvious mark of sexual distinction, is the ovipositor with which the females are provided. This remarkable appendage varies in its form, in fine accordance with the varied economy of different species. Some Ichneumons deposit their eggs on the bodies of caterpillars; an operation which they accomplish by merely piercing the skin. Others, in order to lodge their eggs in a proper receptacle, are obliged to perforate the nests of insects, and to penetrate to the bottom of crevices too narrow to admit of the whole body. The former are furnished with a short, retractile ovipositor, seldom exserted, and lodged in a groove on the under side of the abdomen. But the ovipositor of the latter is often of considerable length, exceeding in some instances that of the whole body. It is composed of three parts; that in the centre is a slender flexile seta, of a corneous substance, very smooth and shining, generally straight and rounded, rarely arcuate and compressed, and most commonly of a rufous or castaneous colour. It is provided with a longitudinal central canal, through which the eggs are propelled. The apex is often compressed and dilated, and impressed with transverse inequalities; it is frequently compressed throughout its whole length, and occasion-

---

[1] In regard, however, to this distinctive character between the sexes, Gravenhorst observes in his preface (page 10)—" nonnullarum mares quoque hoc ornamento gaudent."

ally bent upwards at the extremity. On each side of this central seta is placed another, adapted, by the concavity of the inner surface, to enclose it as in a sheath. These lateral appendages are generally punctate and pubescent externally, and somewhat incrassate towards the apex. They issue from the terminal segment of the abdomen; but the central tube or oviduct originates in the interior, and must necessarily be connected with the viscera, to whose contents it forms the outlet.

When a female Ichneumon, furnished with an apparatus of the kind just described, has discovered the retreat of a larva or pupa, in which she wishes to deposit her eggs, she stations herself immediately over the spot, and raising her abdomen to a vertical position, bends the ovipositor under her belly, and thrusts it into the aperture. This operation is much facilitated by the great flexibility of the instrument, and the ease with which it can be accommodated to any circumstances in which it requires to be employed. It penetrates to a considerable depth into the body of the larva, lest the eggs, by being placed near the surface, should be thrown off when the skin is changed. Upon their exclusion from the egg, the parasitical young make their way still farther into the interior of the larva, consuming the fat that surrounds the muscles and viscera, but carefully abstaining from doing injury to the vital organs. In this state they are gregarious, and were found by Réaumur (who has given a figure of a caterpillar so infested) to be arranged in regular rows in the interior of the caterpillar. When they have arrived at maturity, they undergo their destined change either in the body of the larva which served them as a matrix, or, gnawing a passage through its skin, they construct externally their silk cocoons, and are then converted into pupæ, from which, after a longer or shorter period, they emerge in their declared or perfect form.

A still more remarkable method of rearing its offspring is adopted by the *Ophion luteus*, and probably by all the other species belonging to that genus.[1] The eggs of this insect are deposited on the caterpillar of the Puss Moth (*Cerura vinula*), to which they firmly adhere by means of an elongated pedicle or foot-stalk. When the larvæ are evolved, they do not enter the body of the caterpillar, but remain attached to the columnar appendage, through which they extract, by suction, the juices necessary for their sustenance. The caterpillar dies before it assumes the pupa state, but this event in no case proves fatal to the larvæ, as it either does not occur till they require no further nourishment, or they avail themselves of that principle of accommodation to existing circumstances, which insects possess in such a remarkable degree, and undergo their destined changes as soon as their supply of food begins to be withdrawn.

Ichneumons are generally active and rapid in their motions; many of them, particularly those belonging to the genera *Ichneumon* proper, and *Cryptus*, continually vibrate their antennæ, a circumstance which induced the older writers to call them *Muscæ vibratoriæ;* others, such as the *Ophiones*, are of slower habits, and have not been observed to exhibit this peculiarity in the movements of their antennæ. The larger species fly with considerable celerity, and cannot very readily be approached, unless when engaged in depositing their eggs; an operation with which they are so entirely engrossed, that all regard for their own safety appears to abandon them. They occur in flowers, on the trunks of trees, and on plants; also on walls and in houses; but their favourite places of resort are the flowers of umbelliferous plants. The species furnished with a long ovipositor usually frequent walls and the trunks of trees, for it is in these situations that they find the larvæ on which a singular instinct leads them to deposit their eggs.

Our knowledge is obscure regarding the food of these insects in the perfect state; but it appears to be derived from the vegetable rather than the animal kingdom. We kept one alive, however, during the greater part of a winter on calf-foot jelly. They have often been observed to examine carefully with their mouths the pollen of plants; and it is probable that the pollen, or rather the honey, of flowers, affords them nourishment. Indeed it is expressly affirmed by Fabricius, that it is this material which forms their food. They do not seem to attack or devour other insects, or larvæ, or spiders, but associate with them without offering the least annoyance. It is likely, therefore, that those authors who assert that they are of predatory habits, mistook for Ichneumons certain species of an allied group (*Spheges*), to which they bear resemblance. Whenever they attack a larvæ, it is not for the purpose of employing it as food, but to convert it into a matrix for the reception of their young. But, though they do not devour spiders, as has been asserted, that insidious tribe of creatures is by no means exempted from their destructive visits,—for they oviposit either on the spiders' eggs, or on the dense silky web in which these are frequently enveloped; and the larvæ when excluded consume the substance of the eggs, and are then changed into nymphs and perfect insects within that silken chamber, so carefully constructed for a far different purpose.

The larvæ of the Ichneumonides are without feet. The tissue of their cocoons is of fine silk, usually of a beautiful yellow, or pure white, according to the species. Some, however, are banded with brown and yellow. We have already stated that their positions are various. A remarkable instance is occasionally met with of a *suspended* cocoon. It hangs to the leaves or twigs of the oak-tree, fastened at one extremity by a silken cord. This cocoon is farther remarkable for the manner in which it executes little springs, several inches in height. These are no doubt occasioned by the enclosed larva, which probably has space enough within to admit of its body being bent and retorted, after the fashion of the little worms which we sometimes see vaulting within the hollow walls of an old cheese.

Several Ichneumons are apterous. These Linnæus placed with the Mutillæ. Degeer describes one which proceeded from a ligneous gall which he found upon the stalk of a species of Potentilla. It first attracted his notice by two inflated conical pieces, pointed at the end, attached to the upper and posterior portion of the thorax, and directed backwards. They were moveable at the base, and the insect worked them about in all directions while itself in motion. It was extremely small, and leapt with great activity. As its hinder thighs were not enlarged, Degeer inferred that its springs were produced by curving its abdomen, and then pressing that part forcibly against the plane of its position.

In regard to the situations most favourable for collecting Ichneumonides, we may observe, that wherever other insects, especially in the larva state, abound, there also we may expect to find multitudes of these parasitical depredators. Having so greatly extended our general observations on this interesting tribe, our limits will less easily admit of our entering into descriptive details of genera and species. For these the reader must consult the works to which we have alluded. We shall however

---

[1] Degeer, ii. p. 850, pl. xxix. fig. 15.

Hymenoptera Terebrantia.

enumerate the genera adopted by Latreille. They are as follows: Stephanus, Jur. (Plate CCXXXI. fig. 15 and 16); Xorides, Lat.; Pimpla (ibid. fig. 19); Cryptus, Ophion, and Banchus, Fab., Helw.; Joppa, Fab. (ibid. fig. 21); Ichneumon proper (ibid. fig. 17); Alomya, Fab.; Peltastes, Illiger (ibid. fig. 18); Acænitus and Agathis, Lat.; Bracon, Jur.; Microgaster, Lat.; Helcon, Nees d'Es.; Sigalphus, Lat.; Chelonus, Jur.; Alysia, Lat.[1]

We shall now exhibit a few examples of Gravenhorst's systematic exposition of the Ichneumonides, and these we shall select from British species.

Genus Ichneumon, Grav. Abdomen petiolate, convex; head transverse; scutellum flat or convex; areolet in most instances pentagonal; (ovipositor concealed or sub-exserted).

This genus includes a great many sub-genera, of which we shall choose the first, or that which bears the same name as its principal, viz.

Sub-genus Ichneumon. Abdomen oblong or sub-ovate; the first segment globose, rough, the petiole long, linear, arcuate; areolet pentagonal; antennæ and feet of moderate or medium size; (ovipositor concealed or sub-exserted).

Section 7th of Gravenhorst.

Scutellum pale; the abdomen either with pale markings, or some of the segments entirely yellow, the apical segment black.

I. *luctatorius*, Fab. Linn. Lat. Grav. Length of the male from five to nine, of the female from five to seven and a half lines. The head of the male, with the mouth and face, yellow; of the female, either entirely black, or, with the interior orbits of the eyes, a lateral spot on the clypeus, the palpi and mandibles, yellow, the apex of the latter fuscous. Antennæ of the male porrect, setaceous, half the length of the body, or a little longer, the first joint yellow beneath; those of the female half the length of the body, curved at the tip, from the ninth to the thirteenth, or from the twelfth to the fourteenth joints, white above, the basal joint sometimes ferruginous beneath. Thorax gibbous; with a yellow line or spot before the wings, and another beneath them, one of which is occasionally awanting; the anterior line, in the female, ascending as far as the neck, of which the upper margin, in the male, is at times yellow; the male has sometimes a yellow spot beneath the scutellum. Scutellum yellow. Wings of moderate size, or rather ample, silaceo-hyaline; the stigma fulvous or ferruginous, rarely fuscescent, the radius fuscous or ferruginous; the radix yellow or ferruginous, rarely fuscous; the squamula either yellow or fuscous, with a whitish or rufescent spot; the areolet pentagonal. The feet of moderate size; the anterior femora on the under side, and for the most part at the apex also, yellow, black towards the base, and sometimes entirely black: the intermediate femora, with the apex, sometimes as far as the middle, and in a few cases the whole under surface, yellow; tibiæ yellow, the posterior black or fuscous at the apex; tarsi yellow, or flavo-ferruginous, the posterior with the tips of the joints sometimes blackish. Abdomen of the male elongated, longer sometimes by one half than the head and thorax, of the same breadth or a little narrower than the thorax, from the second to the third segments nearly of equal breadth, the following gradually narrowed towards the extremity; that of the female oblongo-ovate, a little longer than the head and thorax, and of the same breadth, the apex acute; the second and third segments yellow, in some females mixed with ferruginous and the margins fuscescent; the second segment of the males occasionally with a lateral abbreviated fuscous line, the third with a transverse line or two fuscous spots at the base; the fourth generally with a fulvous or rufous spot in the angles at the base, and more rarely the outer margin, or the base, or a lateral mark, rufescent or yellowish; the fifth very rarely with the outer margin yellowish.

The males of this species occur in considerable profusion in Britain, and throughout the greater part of Europe; the females are very rare.[2] They frequent sides of fields, and open places in woods, and are often to be found on umbelliferous plants during the autumnal months. They are liable to great variation both in size and colouring. Roxburghshire, and near Edinburgh, in considerable plenty.

Genus Tryphon, Grav. Abdomen convex, petiolate, or sub-sessile; head transverse; scutellum flat or convex; areolet triangular, or irregular, or absent; (ovipositor concealed, or sub-exserted).

Sub-genus Tryphon. Abdomen oblong, sub-sessile, or sub-petiolate; antennæ slender or middle-sized; feet of moderate length.

Section 4th of Gravenhorst.

Scutellum black, abdomen either entirely rufous, or rufous and black, or yellow and black.

T. *elongator*, Grav. Fab. Length from two and a half to five lines. The mouth generally rufescent, the apex of the mandibles black, or entirely black. The forehead with an erect horn, variable in length, but never exceeding that of the basal joint of the antennæ. Antennæ setaceous, shorter than the body; the first joint black, very rarely ferruginous beneath; the following generally fulvous or ferruginous, fuscous above, sometimes entirely fulvous or ferruginous. Thorax gibbous. Wings most commonly yellow-hyaline; the stigma and radius ferruginous, or pitchy straw-coloured, the radix straw-coloured, the squamula either black or pale ferruginous; areolet irregular or sub-triangular, sub-petiolate or sessile. Feet rather stout, the coxæ and trochanters black; the anterior femora yellow or testaceous, black externally towards the base; the intermediate femora black, with the apex yellow or testaceous, sometimes almost entirely testaceous on the under side; the posterior femora entirely black; the tibiæ yellow, rarely testaceous, the hinder with the apex and base black; the tarsi rufous or rufo-ferruginous, claws fuscous. Abdomen sub-petiolate, generally longer than the head and thorax, and nearly of the same breadth, sub-clavate, or sub-ovate, or fusiform; first segment canaliculate, gradually dilated towards the apex, about one half longer than broad, generally black, with the margin ru-

---

[1] For their characters, see *Règne Animal*, t. v. pp. 285–90.

[2] It is probable that the predominance in number of one sex over the other, so often alluded to by authors as an anomalous fact in the history of Ichneumons, is more apparent than real, and arises, in some instances, from the distinctive marks of sex being so slight as to elude observation, while in others the sexes are so dissimilar that each of them is received as a different species. The determination of the sexes is impeded by the difficulty of observing their intercourse. "Nunquam mihi successit," says Gravenhorst, "par copula junctum aut copulam parans invenire, licet forsan centum millia individua viva Ichneumonidum, in statu eorum libero naturali, viderim, et per triginta annos omnem operam dederim ut copulam viderem." (Vol. i. page 98.)

Hymenoptera Terebrantia.

fous or fulvous, sometimes almost entirely rufous or fulvous, with the base black; the second, third, and fourth segments, sometimes also the base of the fifth, yellow or fulvous. Ovipositor very short, black, generally concealed.

This species abounds in most parts of Europe. It is plentiful in England, and is not unfrequent in Roxburghshire and other southern counties of Scotland. It likewise occurs near Edinburgh.

Genus Alomya, Grav. Abdomen petiolate, convex; head globose; areolet triangular.

A. *ovator*, Grav.; *Ich. ovator*, Fab. Lat.; *Ich. elongator*, Gmel. Oliv. Length from five and a half to seven and a half lines. Head sub-globose, somewhat quadrate when viewed from above, with the angles obtuse, sub-transverse; the face sometimes with a slightly elevated tubercle. Antennæ of the male setaceous, shorter than the body, or nearly of the same length, porrect, entirely black; those of the female moniliform, not half the length of the body, incurved at the apex, from the third to the thirteenth or fourteenth joints, ferruginous or testaceous, gradually becoming paler. Thorax very slightly gibbous. Scutellum triangular, flat. Wings of moderate size, hyaline or smoky-hyaline, the stigma ferruginous or fulvous, the radius piceous, the radix piceous or fuscous or ferruginous, the squamula black or fuscous; areolet pentagonal. The feet of the male with the coxæ and trochanters black; the femora of the fore legs ferruginous or fulvous, generally with the apex sub-testaceous and the base black; those of the middle legs generally black, with the apex ferruginous; those of the hind legs entirely black; the tibiæ yellow or testaceous, the hinder occasionally with the apex fuscous; the tarsi testaceo-ferruginous. The legs of the female are shorter and thicker than in the male, the coxæ, trochanters, and femora black, the latter, in the fore legs, for the most part almost entirely, or the apex only, rufous or ferruginous; the tibiæ either entirely ferrugino-testaceous, or testaceous with the apex ferruginous; tarsi fusco-ferruginous. Abdomen petiolate, convex, elongate; that of the male rather more than one half longer than the thorax, and nearly of the same breadth, the segments from the second to the sixth equally broad; the petiole linear and slender; the colour black and rufous, variously intermingled. Ovipositor concealed.

This species is of frequent occurrence both on the continent of Europe and in Britain. Gravenhorst is of opinion that *Alomya victor*, Curtis, *Ent. Brit.* 120, is a variety of this species.

Genus Cryptus, Grav. Abdomen petiolate, convex; head transverse; scutellum flat or convex; (ovipositor exserted.)

Sub-genus Pezomachus, from πεζομάχος, *a fighter on foot*, because the species, from the imperfect development of the organs of flight, are unable to attack larvæ on the wing. Body small; abdomen petiolate; wings awanting or very small; ovipositor exserted, short, or of ordinary length.

P. *Hopei*, Grav. *Supplementa Partis* ii. vol. i. p. 715. Length from two and a fourth to two and a half lines. Head black, palpi rufous. Antennæ slender, curved, rather more than half the length of the body; from the first to the fifth joint rufous, the sixth or the sixth and seventh fuscous, from the eighth to the eleventh white, rufous beneath, the remainder rufous, fuscous above. Thorax and scutellum rufous; metathorax with two very short obtuse spines. Wings shorter than the thorax. Feet somewhat slender, rufous; the apex of the hinder femora, and sometimes of the tibiæ, black, the base of the latter whitish. Abdomen scarcely longer than the head and thorax, and a little broader, oblong-ovate; the three basal segments rufous; the fourth, with the sides and sometimes the base, also rufous; the fifth and sixth black; the seventh white. Ovipositor rather more than half the length of the abdomen, the sheath black, the tube rufous.

This insect, hitherto found in Britain only, occurs not unfrequently in oak coppices in Roxburghshire, near Minto, Cavers, &c. It is named by Gravenhorst after a distinguished English collector, our honoured correspondent, the Rev. F. W. Hope, by whose effective practical researches the *Ichneumonologia* has been enriched by many new species.

Genus Pimpla, Grav. Abdomen convex, sessile; scutellum triangular or sub-orbicular; (ovipositor exserted).

Sub-genus Lissonota, from λισσὸς, *smooth*, and νῶτος, *the back*, in allusion to the smooth upper surface of the abdomen. The abdomen in most smooth, shining; the apical segments of the female entire on the under side; areolet either awanting or triangular; (ovipositor long).

Section 1st of Gravenhorst.

Scutellum and abdomen black; the latter sometimes with the apical margin of the segments castaneous.

L. *setosa*, Grav.; *Ich. setosus*, Oliv.; *Ich. immaeulatus*, Gmel.? Length from seven to nine lines. Labrum sometimes obscurely ferruginous. Antennæ subfiliform, somewhat incurved and tapering towards the apex, half the length of the body, at times nearly of the same length. Thorax slightly gibbous. Wings of moderate size, smoky-hyaline, the stigma and radius nigro-fuscous, the radix piceo-fuscous or piceo-ferruginous, the squamula black or fusco-ferruginous; areolet sessile or sub-petiolate, triangular. Feet elongate, fulvous, the coxæ black, the posterior tarsi for the most part black or fuscous. Abdomen a little longer and narrower than the head and thorax, or of the same breadth, punctate; that of the male sub-cylindric, somewhat narrowed towards the apex; that of the female oblong or sub-cylindric; the margins of the segments elevated, shining; the first segment sub-canaliculate; the third sometimes fuscous. Ovipositor the length of the body; the tube black or fusco-castaneous, rarely fulvous.

This insect is pretty widely distributed over the north of Europe, and is found occasionally in England.

Sub-genus Pimpla. The segments for the most part transversely impressed, the intermediate ones broader than long, those at the apex having, in the females, a longitudinal groove or fissure on the under side; the areolet triangular; (ovipositor of moderate size, rarely long).

Section 6th of Gravenhorst.

Scutellum, thorax, and abdomen black; the latter sometimes with rufous bands; posterior coxæ black.

P. *examinator*, Grav.; *Cryptus examinator*, Fab.; *Ich. rufescens*, Gmel. Length of the male from one and two thirds to four and a half, of the female from two and a half to six lines. Palpi of the male whitish or yellowish, rarely piceous. Antennæ of the male either entirely black, or ferruginous on the under side towards the tip, with the first and second joints, or the first only, whitish. Thorax of the female, rarely that of the male also, with a whitish or straw-coloured line or spot, sometimes obsolete, before the wings. Wings smoky-hyaline; the stigma and radius black or fuscous, rarely piceous; the radix straw-coloured, in the females for the most part ferruginous or fuscous; the squamula of the male straw-coloured or fuscous, of the female ferruginous or fuscous, generally with a whitish spot, seldom entirely whitish; the areolet irregular, sessile or sub-sessile. Anterior feet rufous or fulvous, the coxæ and trochanters black, in the male sometimes yellow beneath, the tibiæ generally with a pale ring near the base; the posterior legs, with the coxæ, black, having very rarely a rufous mark, or the outer side entirely rufous; trochanters black, the apex in the male generally rufous; femora rufous or rufo-fulvous, the knees sometimes black, the whole outer side in some females black; tibiæ blackish, with a whitish ring near the base, in the male sometimes rufous near the apex; tarsi of the male black, of the female fuscous or fusco-ferruginous. Abdomen of the male longer, and rather narrower than the head and thorax, sub-cylindrical; that of the female a little longer than the head and thorax, sometimes twice the length of the thorax, and of the same breadth, sub-cylindrical or oblongo-ovate; the first segment scrobiculate at the base, the rest with their apical margins somewhat elevated, shining, and generally obsoletely castaneous, in the male sometimes ferruginous. Ovipositor half the length of the abdomen, or a little shorter.

This species usually deposits its eggs on the larva of some kind of moth, and specimens have been obtained from the pupa of *Tinea padella*, and *Bombyx fuliginosa.* It is not a scarce insect on the continent of Europe, and it occurs both in England and Scotland. Near Cavers, Roxburghshire, and in the vicinity of Edinburgh.

Sub-genus Ephialtes. Abdomen long, in most instances tuberculated; the anterior segments, and generally the intermediate ones also, longer than broad, those at the apex with a longitudinal groove on the under side in the females: areolet triangular: (ovipositor long).

E. *manifestator*, Grav.; *Ich. manifestator*, Linn. Length of the male from six to eleven, of the female from nine to fifteen lines. Palpi fuscous or ferruginous, the labrum sometimes obscurely ferruginous. Antennæ filiform, half the length of the body, or a little longer, porrected, often slightly curved at the tip. Thorax occasionally with a minute testaceous or ferruginous spot at the base of the wings. Wings of moderate size, more or less smoky-hyaline, the stigma more or less obscure; radius fuscous, radix and squamula ferruginous or straw-coloured, areolet somewhat regularly triangular, sessile or sub-petiolate. Feet somewhat slender and elongated, fulvous or rufous; the posterior tarsi and tibiæ, and sometimes the knees, fuscous, the tibiæ for the most part ferruginous towards the base, especially on the inner side. Abdomen more than one half, or three times longer than the head and thorax, of the same breadth as the thorax, or a little narrower, cylindrical, black, very rarely fuscous; the first segment canaliculate, the rest more shining, with an obsolete lateral tubercle and elevated margins, the length of the segments from the first to the fifth exceeding their breadth often by one half. Ovipositor longer than the body, rarely of the same length, the sheath somewhat pilose; the tube fuscous or rufo-castaneous, rarely black or straw-coloured, the apex sub-compressed, lanceolate, faintly impressed with transverse lines.

This insect, which is the largest of the European Ichneumonides, occurs not unfrequently in many parts of Europe. It is found in England; and in Scotland it has been observed in Roxburghshire, and near Edinburgh. "On the first of October," says Gravenhorst, "I observed many females of this species on the decaying trunk of a willow, about to deposit their eggs. They traversed with much assiduity the barkless trunk, which was perforated with numerous holes, inhabited no doubt by the larvæ of other insects; and so free were they from apprehension, that when I touched them with my finger they did not fly off, but only slightly averted their bodies. They searched out and examined the holes by means of their antennæ, which were vibrating incessantly, and exploring on all sides. When they had selected a hole, they stationed themselves with the four anterior legs over it, and raising the body as high as possible, and the abdomen perpendicularly, bent the ovipositor downward in such a manner that it passed under the belly and thorax, and entered the hole over which they stood. It not unfrequently happened, when the hole was sufficiently large, that the whole abdomen was inserted, and the head, feet, and thorax were the only parts of the insects which remained free. Frequently also a contest took place between two females for the possession of a hole; but they did not employ their mandibles on these occasions, their fighting consisting entirely of violent concussions of their bodies, and strokes of the feet, till the weaker party retreated. When a female had obtained full possession of a hole, no attack could displace her; but she retained her seat even though assailed by a more powerful antagonist."

GENUS METOPIUS, Grav. Abdomen sessile, convex, rough; scutellum quadrangular, the apical angles acute; (ovipositor concealed).

M. *necatorius*, Grav.; *Peltastes necatorius*, Illiger, Curtis, *Brit. Ent.; Ichn. vespoides*, Panz. Lat. Length from five to seven lines. Face concave, the margins elevated, either entirely or the sides only yellow, sometimes with a broad black line or spot in the middle; palpi at times yellow or ferruginous. Antennæ filiform, a little shorter than the body, seldom entirely black, with the joints from the third to the fourteenth ferruginous beneath, gradually becoming more dusky; for the most part, however, all of them are ferruginous beneath, except the first, which is either entirely black or yellow on the under side. Thorax gibbous, clothed, especially on the sides, with a fine whitish down; a line before the wings, and another, or a spot, beneath them, yellow; sometimes also two spots on the back of the metathorax, and less frequently a lateral spot on the prothorax, and two small dorsal spots before the scutellum, of same colour. Scutellum seldom entirely black, the apical angles, and sometimes the whole apex, yellow. Wings of moderate size, smoky-hyaline, especially towards the radius, fulvo-hyaline towards the apex; stigma and radius ferruginous or fulvous; radix black, rarely testaceo-piceous; squamula black; areolet transversely triangular, somewhat irregular, sessile or sub-petiolate. Feet of moderate size, the posterior femora incrassate; coxæ black; trochanters generally black, with the apex yellow: the anterior femora usually black, with one of the sides more or less yellow or ferruginous; the middle femora sometimes with the apex only ferruginous, rarely black, with the base and apex yellow; the hinder femora generally yellow at the base, with the apex black, very rarely entirely black; the tibiæ yellow or ferruginous, the anterior rarely fuscescent on the outer side; the posterior with the apex more or less blackish, rarely black, with the inner side ferruginous: the tarsi flavo-ferruginous, or ferruginous, the posterior with the joints from the second to the fifth dusky. Abdomen twice the length of the thorax, scarcely narrower, cylindric, punctate; first segment very short, yellow, with the base, and sometimes a longitudinal line in the middle, black; the second with a yellow spot on both sides in the apical angle, sometimes obsolete; from the third to the fifth, and very rarely the sixth also, with the margins, yellow; the terminal segments occasionally somewhat blackish-blue.

This species appears to be pretty generally distributed. It is not unfrequent in England, where it has been observed to issue from the pupa of *Stauropus Fagi.* Mr Curtis conceives this insect to be one of the sexes of *M. dentatus.*

Hymenoptera Terebrantia.

Genus Bassus, Grav. Abdomen sessile, depressed; the first segment flat, of equal breadth; the terminal segments in the female sometimes compressed.

Sub-genus Bassus. Areolet either absent or triangular; antennæ and feet of moderate size or slender; (ovipositor sub-exserted, sub-erect).

B. *flavolineatus*, Grav. Length three lines. The head with a facial spot, the palpi and mandibles yellow, the latter with the apex black. Antennæ porrect, rather longer than the body. Thorax with the suture before the wings, and the lateral one between the prothorax and metathorax, together with a transverse line beneath the scutellum, yellow. Scutellum with the apex yellow. Wings smoky-hyaline, iridescent, the stigma and radius black-fuscous, the radius and squamula yellow. Feet rufous; the fore legs yellowish beneath, the base of the coxæ black; the hind legs with the tarsi and tibiæ black, the latter white at the base. Abdomen slightly depressed, the length of the head and thorax, and a little narrower; the first segment of equal breadth, one half longer than broad; the remainder transverse. Ovipositor very short, sub-exserted.

This species has been taken in England by the Rev. F. W. Hope, near Netley.

Genus Banchus, Grav. Abdomen compressed or sub-compressed, sessile or sub-petiolate.

Sub-genus Banchus. Abdomen sessile, rarely sub-sessile; areolet sub-rhomboidal, the lower external nerve of the interior cell sub-arcuate. (Ovipositor concealed).

B. *falcator*, Grav.; *Ich. venator*, Fab.; *Ich. falcatorius*, Fab. Gmel. Oliv. Panzer. Length from five and three fourths to seven lines. Mouth ferruginous, mandibles black at the base and apex, the external orbits of the eyes, rarely the internal also, yellow or ferruginous. Antennæ half the length of the body, or a little longer, slender and incurved towards the apex, beneath rufous or ferruginous, rarely fusco-ferruginous. Thorax gibbous, generally with a short sub-testaceous line below the insertion of the wings. Scutellum tuberculate, rarely sub-acuminate, sometimes ferruginous, very rarely yellow. Wings middle sized, fulvo-hyaline or somewhat smoke coloured; the stigma, radius, radix, and squamula fulvous, rarely ferruginous, the latter sometimes with a fuscous spot. Feet elongate, fulvous, for the most part yellow beneath, the coxæ black, occasionally with a ferruginous mark; the hinder tibiæ black at the apex, the tarsi ferruginous or ferrugino-fuscous. Abdomen longer than the head and thorax; the first segment gradually a little narrowed towards the apex, nearly one half longer than broad; from the first to the fourth segment narrower than the thorax, the back fusiform, the belly compressed; from the fifth to the seventh angular, the back, sides, and belly compressed; the first segment seldom wholly black, the apex being generally brown or rufous or fulvous; the second seldom wholly rufous, or black with a dorsal rufous spot, but most commonly brown or rufous with the base black, or the base rufo-ferruginous, the apex fulvous-yellow; the third with the back either entirely rufous, or the base black or the apex yellow, but more commonly black, with the base and a point at the apex rufous; the fourth sometimes, rarely also the fifth, sixth, and seventh, with the apex of the back, rufous.

The female of this species differs considerably from the male, particularly in the markings of the head and thorax. Neither of the sexes is rare, as they have been taken abundantly both on the continent and in England.

Genus Ophion, Grav. Abdomen compressed or sub-compressed, petiolate; antennæ filiform.

Sub-genus Paniscus. Abdomen sub-petiolate compressed, the back carinate; areolet triangular; the feet and antennæ somewhat slender; (ovipositor short).

P. *testaceus.* Length of the male from three to nine, of the female from three and three fourths to eight lines. The mandibles black at the apex, the face sometimes yellowish; the eyes and ocelli, sometimes also the hinder part of the head, fuscous or black. The antennæ for the most part obscure or fuscescent at the tip; in the male rarely fuscous or blackish, the base testaceous-ferruginous. Thorax sometimes with longitudinal fuscescent lines on the back. Wings hyaline or somewhat yellow-hyaline; the stigma testaceous or straw-coloured, in the male sometimes fuscescent, the radius fuscous or testaceous, the radix and squamula testaceous; areolet irregular sub-sessile, generally semi-complete, the lower portion of the exterior nerve obsolete. Feet fulvous, rarely ferruginous in the male, the hinder tarsi at times of a paler hue. Abdomen longer, sometimes by one half, than the head and thorax, compressed, the apex in the male obtuse, in the female truncate; testaceous, often fuscescent towards the apex, or somewhat fusco-fulvous towards the base; the sixth, seventh, and apex of the fifth segment, very rarely black-fuscous; the first segment gradually dilated towards the apex, five or six times longer than broad, the anterior portion nearly one half longer than the petiole. Ovipositor the length of a fifth or sixth part of the abdomen, black, the tube castaneous or fuscous.

This insect is of frequent occurrence throughout the south of Scotland in the autumn. It is likewise plentiful in England, and on the continent. It deposits its eggs on the larvæ of various moths, and occasionally on those of the genus *Tenthredo.*

Sub-genus Ophion. Abdomen petiolate, compressed, the back carinate; areolet absent, the interior cell receiving the two recurrent nerves; feet and antennæ slender, long; (ovipositor scarcely sub-exserted).

O. *luteus*, Grav. Fab.; *Ich. luteus*, Linn. Lat. Length of the male from six to nine, of the female from four to nine lines. The head in most individuals entirely rufous, or the internal orbits of the eyes yellow; rarely yellow, with the mouth and face, excepting the internal orbits of the eyes, rufous; very rarely entirely yellow; mandibles black at the apex: eyes and stemmata fuscous or blackish. Antennæ either a little longer or a little shorter than the body. Thorax testaceous or rufous, very seldom rufo-ferruginous, the prothorax with two longitudinal pale lines. Scutellum for the most part pale, sometimes yellow. Wings hyaline or somewhat smoky-hyaline; the stigma, radius, radix, and squamula fulvous or testaceous, the upper exterior nerve of the interior cell very seldom incrassate towards the stigma; in most instances, however, the rudiment of the nerve dividing the interior cell is observable, and it is sometimes produced as far as the middle, rarely beyond the middle of the cell. Abdomen testaceous, seldom rufous, the belly generally fuscescent, sometimes also fuscescent or blackish towards the apex. Ovipositor scarcely sub-exserted, blackish.

This species is pretty generally distributed over the western parts of Europe, and occurs not unfrequently in England. The female deposits her eggs on the larvæ of *Cerura vinula*, *Noctua præcox*, and other moths. "Ils y sont fixés," says Latreille, "au moyen d'un pedicule long et delié. Les larves y vivent, ayant l'extrémité postérieure de leur corps engagée dans les pellicules des œufs d'où elle sont sorties, y croissent, sans empêcher la chenille de faires sa coque; mais elles finissent par la tuer, en consumant sa substance intérieure, se filent ensuite des coques, les unes auprès des autres, et en sortent sous la forme d'ichneumons."[1] The larvæ of another species, *O. moderator*, Fab. destroy those of its ally *Pimpla strobitellæ*.

Genus Hellwigia. Abdomen petiolate, compressed; antennæ clavate.

H. elegans. Grav. Length from five to six lines. Head thick and closely punctate, with two deep irregular foveæ on the forehead, and a longitudinal groove between the antennæ; that of the male yellow, the occiput, foveæ, and apex of the mandibles black; that of the female black, the external orbits of the eyes yellow. Antennæ porrect, dilated at the apex a little more than half the length of the body, and composed of about thirty joints; in the male fulvous, yellowish on the under side towards the base, the first joint fuscous above; in the female rufous, the first three joints black. Thorax short, gibbous; two simple or hook-shaped spots before the neck, a short line under the anterior wings, two points or a single one under the posterior wings, a perpendicular line or point at the sides of the thorax, a point under the scutellum, a large semilunar spot on the metathorax, and another on each side of it, yellow: all these markings in the male are larger and more contiguous. Scutellum yellow. Wings middle-sized, hyaline, the stigma straw-coloured, the radius and nervures piceous or fuscous, the radix and squamula yellow. Feet middle-sized, sub-elongate; those of the male entirely yellow, the posterior tarsi rufescent towards the apex, the joints from the second to the fourth black at the base; the anterior feet of the female yellow, the coxæ black, with a small apical yellow spot, the trochanters black at the base; the hinder feet fulvous, the coxæ black, with a yellow spot, the trochanters yellow, the base black. Abdomen nearly one half longer than the head and thorax; the first segment flaggon-shaped, shining, very smooth, the anterior part scarcely longer than broad, shorter, and one half broader than the petiole; in the male the first segment black, the apex yellow, from the second to the fourth testaceous-rufous or yellow, with the base sub-rufescent, from the fifth to the seventh yellow, the fifth, and sometimes the sixth also, with the base, blackish at the side; in the female the first, fifth, sixth, and seventh segments black, with the margin yellow, the intermediate segments fulvous or rufous, with the margin for the most part yellow. Ovipositor scarcely sub-exserted, black.

The preceding examples will suffice to illustrate Gravenhorst's mode of treating the Ichneumonides. We shall now proceed to

Tribe 3d, Gallicolæ.[2]

These have only a single nervure on the lower wings; the upper pair offer a few areolets or cells, viz. two at the base—the brachial, of which the internal is usually incomplete or slightly marked,—one radial and triangular,—and two or three cubital,—of which the second, in such as have three, is always very small, and the third very large, triangular, and closed by the posterior margin of the wing. The antennæ are either of equal thickness, or increase towards the termination, but not club-shaped, and are composed of from thirteen to fifteen articulations, the number when different in the sexes being generally greater in the males. These insects form the old genus Cynips of Linnæus (Plate CCXXXI. fig. 20). Their general form is humped or gibbous, with the head small, and the thorax thick and elevated. The abdomen is compressed, carinated, or cutting inferiorly, and truncated obliquely, or obtuse, at the extremity. It is furnished in the females with an ovipositor, which seems to consist of only a single piece, long and delicate, or capillary, spirally rolled at its base, and attached near the origin of the abdomen. It is minutely described by Réaumur.[3] With this admirable instrument it deposits its eggs in the leaves and stems of various plants, and on these its punctures produce those peculiar excrescences known by the name of gallnuts, so useful when employed along with a solution of green vitriol, or sulphate of iron, in dyeing blacks. Some of these insects are apterous. "Une espèce," says Latreille, "dépose ses œufs dans la semence du figuier sauvage le plus précoce. Les Grecs modernes, suivant à cet égard une méthode que l'antiquité leur a transmise, enfilent plusieurs de ces fruits, et les placent sur les figuiers tardifs; les Cynips sortent chargés de poussière fécondante, s'introduisent dans l'œil des figues de ces derniers, en fécondent les graines et provoquent la maturité du fruit."[4] This is the process known abroad by the name of *caprification*.

The genera of this tribe are Ibalia and Figites, Lat. and Cynips proper (*Diplolepis* of Geoff.). Of the genus last named we have figured *C. rosæ*, its larvæ, and the gall in which the latter dwell (Plate CCXXXI. fig. 20, 22, 23, 26, 27, 28).

Tribe 4th, Chalcidiæ.

These do not differ very materially from the preceding, except in the antennæ, which, with the exception of *Eucharis*, are geniculate, and form, subsequent to the bend, an elongated or fusiform club, of which the first articulation is not unfrequently lodged in a groove. The palpi are extremely short. The radial cell is usually wanting, and there is never more than a single cubital cell, which is not closed. The antennæ have not more than twelve articulations. The modern genera are very numerous, though all related to the genus Chalcis of Fab. The species are extremely small, brilliantly ornamented with metallic colours. Many of them are leapers. The ovipositor is generally composed of three threads, like that of the Ichneumons, and is salient. The larvæ likewise resemble those of that tribe in being parasitical, and some of them are so minute as to be able to dwell at large in the interior of insect eggs, themselves scarcely visible to the naked eye.

We shall here mention only two genera of the tribe, of each of which we have figured an example. *Chalcis minuta* (Plate CCXXXI. fig. 25), synonymous with *Vespa minuta* of Linn., is extremely common on umbelliferous flowers. It is black, with yellow feet. Another species, *C. annulata*, Fab., inhabits the nest of the pasteboard wasp of South America (*V. nidulans*), and appears to have been mistaken by Réaumur for the female of that insect. Our other representative, *Leucospis dorsigera* (ibid. fig. 24), is black, with the abdomen almost as long again as the thorax, and marked with three bands and two spots of yellow. There is a transverse yellow line upon the scutellum, and two others of the same colour on the anterior portion of the thorax. The female deposits her eggs in the nests of mason-bees.[5]

Mag.* 3d series, No. 3); Mr Halliday's *Essay* on the same subject in *Entom. Mag.* No. 3; Mr Walker's *Monographia Chalcidum*, published in the initiatory numbers of the last-named periodical; and a similar *Monograph* by M. Boyer de Foscolombe, in the *Ann. des Sciences Nat.* for July 1832.

TRIBE 5TH, OXIURI, Lat.

This tribe resembles the preceding so far as concerns the want of nervures in the lower wings, but the abdomen of the female is terminated by a tubular and conical ovipositor, sometimes internal and exsertile, proceeding like a sting from the anal extremity, sometimes permanently external, and forming a kind of tail. The antennæ are composed of from ten to fifteen articulations, and are in some cases filiform or slightly enlarged towards the extremity, in others clubbed in the females. The maxillary palpi in several are long and pendant.

The minor genera which compose this tribe are all more or less related to the genus BETHYLUS of Fabricius and Latreille. The only example we have here adduced is that of *Diapria elegans* (Plate CCXXXII. fig. 1), an insect belonging to a genus in which the wings have no cells. The maxillary palpi are projecting, and the antennæ have fourteen joints in the male, and only twelve in the female.[1]

TRIBE 6TH, CHRYSIDES, Lat.

This tribe agrees with the three preceding in the want of nervures in the lower wings; but the ovipositor of the female is formed by the terminal segments of the abdomen, which somewhat resemble in their construction the tubes of a telescope, and are terminated by a little sting.[2] The abdomen, which in the female seems to be composed of only three or four segments, is arched or plain beneath, and is capable of being applied against the chest,—in which attitude the insect assumes the form of a ball. This tribe includes the old genus CHRYSIS of Linnæus, and is remarkable for the extreme richness and brilliant lustre displayed by the colouring of many species. In these respects they rival the gorgeous humming-birds, and are known under the name of gilded wasps,—the *guepes dorées* of our continental neighbours. They are lovers of the cheerful sunshine, and during the bright days of early summer may be seen moving about in a state of great vivacity, almost of agitation, on walls, old timber, and other objects exposed to the gladdening influence of heat and light. They are also found on flowers, "beautifying the beautiful," and adding to their gorgeous petals all that is wanting to complete the glory of the "lilies of the field,"—a burnished or metallic lustre.[3]

The body of these insects is covered by a very solid integument. Their antennæ are filiform, geniculate, vibratile, and composed of thirteen articulations in both sexes. The mandibles are arched, narrow, and pointed. The maxillary palpi are usually longer than the labial, filiform, and composed of five unequal articulations;—the labial consist of three. The ligula is for the most part emarginate. The thorax is semicylindrical, and exhibits several impressed and transverse lines. The abdomen in the greater number is semi-oval, truncated at the base, and appears at first sight as if attached to the thorax by its entire breadth. The terminal segment is frequently marked by large punctures, and terminates in dentations.

These beautiful creatures deposit their eggs in the nests of the solitary mason-bees, and in those of other Hymenoptera. Their larvæ sustain themselves by devouring the lawful inhabitants.

In some, such as the genus PARNOPES, Lat. (Plate CCXXXII. fig. 2), the maxillæ and labrum are very long, and form a kind of false proboscis, bent underneath. The palpi are small and biarticulate. The example figured, *P. carnea*, deposits its eggs in the nest of *Bembex rostrata*. In CHRYSIS proper there is no false proboscis. The maxillary palpi are of medium size, or elongated, and composed of five articulations; the labial consist of three. Several analogous genera are recognised by naturalists, such as HEDYCHRUM, Lat. (Plate CCXXXII. fig. 3), in which the maxillary palpi are much longer than the labial, the ligula emarginate, and the abdomen rounded and entire at the extremity.[4]

ACULEATA.[5]

This, the second primary section of the hymenopterous order, is distinguished from the preceding by the want of an ovipositor. That organ is represented by a sting composed of three parts, concealed and retractile. It is characteristic of the females, and likewise exists in those individuals (imperfect in a sexual point of view) commonly called neuters, which constitute so important a feature in the social union of the gregarious kinds. It is, however, wanting in several of the ant tribe,—in which case the insect defends itself by ejecting an acid liquid, elaborated and contained in special reservoirs.[6] Our present Hymenoptera have always simple antennæ, composed of a constant number of articulations, that is, thirteen in the males and twelve in the females. The palpi are usually filiform; those of the maxillæ, which are frequently the longer, have six articulations,—the labial only four. The mandibles of the males are smaller, and generally less toothed, than in the others. All the wings are veined. The abdomen, united to the thorax by a thread or pedicle, is composed of seven segments in the males, and of six in the females.

The larvæ in this family are never furnished with feet. Their food is supplied to them by females or neuters, and varies in its nature according to the different kinds. Latreille divides the section into four families.

FAMILY I.—HETEROGYNA.[7]

The species of this family consist of individuals which differ from each other not only in their sexual characters, but in the presence or absence of the wings, and in other particulars. In all, the antennæ are geniculate, and the ligula small, rounded and hollowed, or spoon-shaped.

Some live in society, and consist of three kinds of individuals, of which two, that is, the males and females, are winged, and the third or neuters are apterous. In the two latter kinds the antennæ gradually increase in thickness, and the length of the first articulation equals at least the third part of their total extent; the second is almost as long as the third, and has the form of a reversed cone. The labrum of the neuters is large and corneous, and falls perpendicularly beneath the mandibles. These Hymenoptera comprise the genus FORMICA of Linnæus.

As a separate treatise under the article ANT[8] has been already devoted in this work to the elucidation of the history and habits of these admirable insects, so long noted for their foresight and industry, we shall not occupy our remaining space by repetition, but shall proceed to a brief sketch of the classification of the species, as promised at the conclusion of the article just referred to. Latreille divides the genus Formica as follows:—

---

[1] For the other genera, see *Règne Animal*, t. v. pp. 300–2; *Genera Crust. et Insect.* t. iv.; Dalman's *Analecta Entomol.*; and Jurine's *Hyménoptères.*

[2] The details are given by Degeer in his *Mém. sur les Insectes*, t. ii. p. 834, pl. 28.

[3] In as far as we are competent to judge, plants and the mammalia seldom seem to exhibit a metallic surface. But that glowing adornment is frequent among foreign birds, and the subjects of our present treatise.

[4] See a *Monograph of the Chrysides*, by Pelletier de St Fargeau, in the *Ann. des Sciences Nat.* t. vii. p. 115.

[5] From *aculeus*, a sting.

[6] *Journal de Physique*, September 1828.

[7] From ἑτερος, *other* or *different*, and γυνη, *female.*

[8] See vol. iii. p. 239.

1*st*, The genus FORMICA properly so called. These want the sting; the antennæ are inserted near the front; the mandibles are triangular, dentated, and incisive; and the pedicle of the abdomen is never composed but of a single squama or knot.

Of the European species we may mention *F. rufa*, Lat., of which the workers measure about four lines in length, and are of a blackish colour, with a great part of the head, the thorax, and the knot, fulvous. The thorax is uneven. The stemmatic eyes are discernible. This species builds in woods, and forms a dome-like or sugar-loaf shaped habitation of considerable size, composed of earth and fragments of wood, &c. Formic acid is obtained chiefly from this insect. The winged individuals make their appearance in spring. (Plate CCXXXII. fig. 4.) *F. sanguinea*, Lat., resembles the preceding in its workers; but the colour is sanguine red, with an ashy-black abdomen. It likewise dwells in woods, and is one of the species named Amazons or *légionnaires* by M. Huber. *F. cunicularia*, Lat., has the head and abdomen of the workers black. Around the mouth, the under parts of the head, the first joint of the antennæ, the thorax, and feet, pale fulvous. The worker of *F. fusca*, Linn., is of an ashy-black, shining, with the base of the antennæ and the feet reddish. The squama or knot is large, almost triangular, and there is an appearance of three stemmatic eyes. Both these species are attacked by the Amazons, carried off, and enslaved.

2*d*, The genus POLYERGUS, Lat. In these the sting is likewise wanting; but the antennæ are inserted near the mouth, and the mandibles are narrow, arcuated, or strongly hooked. In this genus is placed the *F. roussatre* of Lat. so common in France. It is this species which is more particularly named Amazon by M. Huber the younger.

3*d*, The genus PONERA, Lat. In these the workers and the females are armed with a sting. The pedicle of the abdomen is formed of a single scale or knot; the antennæ of the individuals just mentioned are thickened towards the extremity; the mandibles are triangular, and the head is also nearly of that form, without remarkable emargination at its posterior extremity. *F. contracta* of Lat., which occurs near Paris, belongs to this division. The worker seems scarcely provided with eyes, and lives under stones in not very numerous groups. It is very small, black, nearly cylindrical, with the antennæ and feet of a yellowish brown.

4*th*, The genus MYRMICA, Lat. In these there is also a sting; but the pedicle of the abdomen is formed of two knots. The antennæ are exposed, the maxillary palpi are long, with six distinct articulations, and the mandibles are triangular. Such is the *fourmis rouge* of Latreille, of which the worker is reddish, finely chagrined, with the abdomen smooth and shining. There is a spine upon the first knot of the pedicle, and the third segment is brownish. This species occurs in woods, and bites sharply.

5*th*, The genus ATTA of Fabricius, which scarcely differs from Myrmica, except by its very short palpi, of which the maxillary are composed of less than six articulations. The head of the workers is usually very large. The species which serves as the type of the genus in the works of Fabricius, Jurine, and Latreille, is the *fourmis de visite*, or *Atta cephalotes* of systematic writers. It is a foreign insect, and seems to agree with that figured by Madame Merian.[1] This creature burrows in the earth, to the extent, it is said, of six or eight feet. It however leaves its subterranean dwelling for a time once a year, and enters dwelling-houses, where it attacks and destroys every other kind of inconvenient insect. If during these predatory incursions they find an intervening space which they cannot cross, a party volunteer to form a chain of their own bodies linked together, over which, as by a bridge, the main body passes.

6*th*, The genus CRYPTOCERUS of Lat., of which the species are also furnished with a sting, and have the abdomen of the pedicle formed of two knots; but the head, which is large and flat, has a groove on each side for the reception of a part of the antennæ. They are peculiar to South America.[2]

The other Heterogyna live in solitude, and each species is composed of only two kinds of individuals, winged males and apterous females,—the latter always provided with a strong sting. The antennæ are filiform or setaceous, vibratile, with the first and third articulations elongated; the length of the former, however, never equalling that of the third part of the total length of the antennæ. They form the genus *Mutilla* of Linnæus, which has been subdivided into DORYLUS, Fab. (Plate CCXXXII. fig. 6), peculiar to Africa and the East Indies; LABIDUS, Jurine, proper to South America; and MUTILLA properly so called (ibid. fig. 5). Of the latter, *M. Europæa*, Linn., is black, with a red thorax, and three white bands on the abdomen. The female is armed with a powerful sting. The manners of the Mutillæ seem little known. We are not ourselves acquainted with the nature of their metamorphosis. They love warm sunny places, and sandy soils. The females being apterous, are always found pon the ground, concealed under stones, or lurking in little holes. The males are seen on flowers, or by the sides of dusty paths, and other places frequented by the females. The genus is extensive, Olivier and Klug having described a great many species.[3]

FAMILY II.—FOSSORES.[4]

This family comprises such of the stinging Hymenoptera as are winged in both sexes, and of solitary habits. The legs of several are adapted for digging. The ligula is always more or less widened at the extremity, and never filiform or sectaceous. The wings are always extended. The old genus SPHEX is the principal representative of this family.

The females of these insects deposit their eggs in little prepared chambers in the earth or in wood, and place alongside of them a supply of insects or their larvæ. They also pierce spiders with their stings, and close them up as provision for their young. The larvæ are without feet, and spin a cocoon before passing into the nympha state. The perfect insects are in general extremely active, and live among flowers. The maxilla and the labium are elongated, and assume in several the form of a trunk. The numerous minor genera derived in recent times from the genus just named, are distributed by Latreille into seven principal tribes.

---

[1] *Insectes de Surinam*, ed. of 1726, p. 18, tab. 18.

[2] Besides the article ANT of this work, see the noted volume by Huber the younger, entitled *Recherches sur les Mœurs des Fourmis indigènes*, and Latreille's *Histoire Naturelle des Fourmis*.

[3] In *Encyclop. Méth.* and *Act. Phys. Med. Acad. Cæsar. Leopold*, t. x. pars 2. Latreille has also published a monograph of the French species in the *Actes de la Soc. d'Hist. Nat. de Paris*, and a great number are figured by Coquebert in his *Iconographia Insectorum*.

[4] From *fossor*, a digger.

In the first two the eyes are often emarginate. The body of the males is usually narrow, elongated, and terminated posteriorly, in a great number, by three spinous points or dentations.

TRIBE 1ST, SCOLIETES, Lat.

The first segment of the thorax is sometimes in the form of a bow, and prolonged laterally as far as the wings, sometimes of a transverse square, or resembling a knot or articulation. The legs are short, thick, very spiny or ciliated, with the thighs arched near the knee. The antennæ are sensibly shorter than the head and thorax in the females. The genera are TIPHIA, Fab. (Plate CCXXXII. fig. 7); MYZINE, Lat.; MERIA, Illiger; and SCOLIA, Fab. (ibid. fig. 8).[1]

TRIBE 2D, SAPIGYTES.

The first segment of the thorax is formed like that of the preceding group, and the legs are also short, but slender, and neither spiny nor strongly ciliated. The antennæ in both sexes are at least as long as the head and thorax. The body is usually either smooth, or but slightly pubescent. The genera are THYNNUS, Fab.; POLOCHRUM, Spinola; and SAPYGA, Lat.

TRIBE 3D, SPHEGIDES, Lat.

These still resemble the preceding in the extent and form of the first segment of the thorax; but the posterior legs are at least once again as long as the head and thorax. The antennæ are often slender, formed of lengthened articulations, lax, or not compactly set, and curved or arcuated, at least in the males.

Of this tribe a certain number have the first segment of the thorax of a square form, whether transverse or longitudinal, and the abdomen is attached by a very short pedicle. The inner side of the posterior tibiæ is usually furnished with a brush or pellet of hairs. The upper wings have three or two complete or closed cubital cells, and a terminal one which is imperfect. The genera are PEPSIS, Fab. (Plate CCXXXII. fig. 9), of which the species, abundant in South America and the Antilles, are large, with coloured wings; CEROPALES, Lat.; POMPILUS, Fab. (ibid. fig. 10), of which the species feed their young with spiders; PLANICEPS, Lat.; and APORUS, Spinola.

Others of the same tribe have the first segment of the thorax narrowed in front, in the form of a knot or joint; and the first segment of the abdomen, and sometimes even a portion of the second, narrowed into an elongated pedicle. The upper wings always exhibit three complete cubital cells, and the commencement of a fourth. The genera are, AMMOPHILUS, Kirby, of which we may mention, as an example, *Sphex sabulosa*, Linn., the female of which digs holes in the earth by the sides of paths and highways, in which she deposits a caterpillar mortally wounded, and then lays an egg beside it,—the said egg soon producing another larva, which, though much smaller, being in good health, immediately eats the sick one; SPHEX, PRONÆUS, CHLORION,[2] and DOLICHURUS, Lat.; AMPULEX, Jur.; PODIUM and PELOPÆUS, Lat.

TRIBE 4TH, BEMBECIDES, Lat.

In these the first segment of the thorax forms only a linear and transverse border, of which the two lateral extremities are distant from the origin of the upper wings. The legs are always short, or of moderate length. The head, seen from above, appears transverse, and the eyes extend as far as the exterior border. The abdomen forms an elongated semi-cone, rounded on the sides, near the base. The labrum is entirely exposed, or very salient.

Of this tribe the species are characteristic of the warmer countries of the earth. Their body is elongated, pointed posteriorly, almost always varied with black and yellow, or reddish, and smooth. The antennæ are approximate at the base, slightly geniculate at the second article, and enlarged towards the extremity. The mandibles are narrow, lengthened, dentated on the inner side, and crossed. The tibiæ and tarsi are provided with little spines or cilia, which are particularly obvious on the anterior tarsi of the females. There are frequently one or two raised teeth beneath the abdomen of the male. The flight of these insects is extremely rapid, and they dart from flower to flower with a sharp and interrupted sound. Several species smell of the odour of roses.

In a certain number we find a false trunk, bent underneath, with the labrum in the form of an elongated triangle.

Of these, some have the palpi very short; the maxillary possessing four, the labial two articulations. Such is *Bembex rostrata*, Fab. (*Apis rostrata*, Linn.), Plate CCXXXII. fig. 11, a large black insect, with transverse bands of citron yellow upon the abdomen. This is a well-known European species. The female digs deep holes in a sandy soil, in which she places the carcasses of other insects, especially Syrphi, and other two-winged flies. Among these she lays her eggs, and then places a plug in the hole. Another hymenopterous insect, however, *Parnopes carnea*, possesses a strong instinctive desire to deposit her eggs in the subterraneous nest of the Bembex. As soon as the latter perceives its natural enemy hovering around its dwelling, it attacks it with the greatest fierceness, and endeavours to thrust its sting through its body,—an attempt, however, which is seldom successful, owing to the hardness of the Parnopes's skin. Others have the maxillary palpi elongated, and with six articulations,—the labial with four. Such is the genus MONEDULA of Lat.

In the remainder of this family there is no false trunk, and the labrum is short and rounded, *e. g.* the genus STIZUS of Jurine.

TRIBE 5TH, LARRATES, Lat.

These in their general aspect resemble the preceding, but their labrum is either entirely or in great part concealed, and there is a deep emargination on the inner side of the mandibles,—a character which distinguishes them both from those which precede and those which follow.

In some the upper wings have three closed cubital cells, of which the second receives the two recurrent nervures. Such are the genera PALARUS, Lat., LYROPS, Illiger, and LARRA, Fab. (Plate CCXXXII. fig. 13). In others the upper wings have only two closed cubital cells, each of which receives a recurrent nervure. Such are DINETUS and MISCOPUS, Jurine.

TRIBE 6TH, NYSSONES, Lat.

In this family the labrum is likewise entirely or in great part concealed. The maxillæ and labium do not form a trunk, and the mandibles have no emargination on the inner side. The head is of ordinary size, and the abdomen is triangular or ovoid-conical, becoming gradually narrower from the base towards the extremity, and never borne upon a long pedicle. The antennæ are filiform, with the first articulation slightly elongated.

---

[1] For the anatomy of the Scoliæ, see Dufour's Observations in the *Journal de Physique* for September 1818.

[2] For the singular habits of *C. compressum*, common in the Isle of France, where it attacks, slays, and carries off cockroaches to its young, see Sonnerat's *Voyage aux Indes Orientales*; Réaumur's *Mémoires*, t. vi. p. 280; or the *Dict. Class. d'Hist. Nat.* t. iv. p. 42.

In the genera Astata, Nysson, Oxybelus,[1] and Nitela, Lat., the eyes are entire; in Pison of Spinola they are emarginate.

Tribe 7th, Crabronites, Lat.

In this, the concluding tribe of Fossores, the head is usually very large, and when viewed from above seems almost square. The antennæ are often enlarged towards the extremity, or club-shaped. The abdomen is either oval or elliptical, and broadest about the middle,—or narrowed at the base into a lengthened pedicle, and as if terminated by a club.

In some the antennæ are inserted beneath the middle of the anterior part of the head, and the chaperon is short and broad. In the genus Trypoxylon, Lat. the eyes are emarginate. Of these, one of the most remarkable is *T. figulus* (*Sphex figulus* of Linn.), Plate CCXXXII. fig. 13. The female deposits her eggs in holes in old timber, along with a supply of little spiders, which she closes up with moist earth. In the remainder the eyes are entire. In the genus Crabro of Fab. (ibid. fig. 15) many of the males are remarkable for a peculiar dilatation of the anterior tibiæ, resembling a slender shell, convex without and concave within, and pervaded by a multitude of little holes, or rather of transparent points. They somewhat resemble the well-known expansions on the fore-feet of the male Dytisci, and probably serve for the same end.[2] In the perfect state these insects seem to feed on the nectareous juices of flowers; but the larvæ are extremely greedy of animal food. The female parent forms holes in the earth, in each of which she deposits an egg along with the body of a captured insect. She then, as usual, closes up the orifice, and the entombed prey, whether dead or alive, is soon attacked and eaten by the young larva to which the egg gives birth. Dipterous insects form their most frequent food, although *C. cribrarius* is observed to seize upon the caterpillar of a *Pyralis* which inhabits the oak. Walckenaer observed several species hovering incessantly around the nests of a solitary bee named *Halictus terebrator*, which they seemed much inclined to enter.[3] The remaining genera of this division of the Crabronites are Stigmus, Jur.; Pemphedron, Lat., of which *P. unicolor* feeds its young on Aphides; Mellinus, Fab. (Plate CCXXXII. fig. 16); and Alyson, Jurine.

In other Crabronites the antennæ are inserted higher up or towards the middle of the face, and are usually enlarged towards the termination, or even club-shaped. In the genus Psen of Lat. the clypeus is almost square, and the abdomen is borne upon an abruptly formed and elongated pedicle, composed of the first segment. The mandibles terminate in two teeth. In Philanthus of Fab. the clypeus is trilobed, and the first segment of the body is at most restricted in the manner of a knot. The mandibles terminate in a simple point. The females of this genus dig holes in the sand, in which they bury the carcasses of bees, Andrenæ, and even of Curculionides, for the nourishment of their young.[4]

FAMILY III.—DIPLOPTERA.[5]

This is the only family of the section in which the upper wings are longitudinally folded.[6] The antennæ are generally geniculate, and clubbed, or enlarged towards the extremity. The eyes are emarginate. The prothorax is prolonged posteriorly on each side to the origin of the wings, of which the superior have three or two closed cubital cells, the second of which receives the two recurrent nervures. The body is smooth, or nearly so, black, and more or less spotted with yellow or fawn colour. Many of the species dwell in temporary societies, composed of three kinds of individuals, males, females, and workers or neuters. A few females which have withstood the rigour of the winter season commence the building of the nest, and attend to the young first produced, which are usually neuters—and these speedily aid their parent in all matters of household management. The family is composed of two tribes.

Tribe 1st, Masarides.

In these the antennæ seem at first sight to be composed of only eight articulations; the eighth forming with the ensuing ones an almost solid mass, rounded or obtuse at the end, with the articulations indistinct. The ligula is terminated by two threads capable of being withdrawn within a tube formed by its base. The upper wings have only two complete cubital cells. The middle of the anterior margin of the clypeus is emarginate, and receives the labrum in that emargination. The genera are few in number. In Masaris proper (Plate CCXXXII. fig. 17), the antennæ, a little longer than the head and thorax, have the first article lengthened, and the eighth forming an obconic club, rounded at the extremity. The abdomen is long. In Celonites, Lat. the antennæ are scarcely longer than the head, and their first two articulations are much shorter than the third; the eighth and following form an almost globular body. The abdomen is scarcely longer than the thorax.

Tribe 2d, Vespiariæ.

In these the antennæ always exhibit distinctly thirteen articulations in the male and twelve in the female, and terminate in an elongated mass, pointed, and sometimes hooked (in the males) at the end; they are always geniculate, at least in the females and neuters. The ligula is sometimes divided into four plumose filaments, sometimes into three lobes, having four glandular points at the end, one on each lateral lobe, and the two others on the intermediate one, which is larger, widened, and emarginate or bifid at the extremity. The mandibles are strong and dentated. The clypeus is large. Beneath the labrum there is a little piece in the form of a ligula, analogous to that which Réaumur observed in certain bees (bourdons), and which M. Savigny names *epipharynx*. With the exception of a small amount of species, the upper wings have three complete cubital cells. The females and neuters are armed with a very strong and venomous sting. Several species live in societies composed of three kinds of individuals.

---

[1] The Oxybeli lay their eggs in little nests in sandy soils exposed to the sun. They store up a collection of dead flies for the use of their young.

[2] See Degeer, *Mémoires*, t. ii. p. 810, pl. 28.

[3] *Mémoires pour servir à l'Histoire Naturelle des Abeilles solitaires.*

[4] We have been under the necessity of doing little more than indicate the names of the generic groups in the family of Fossores. For the details the reader is referred to the corresponding articles in the *Encyclop. Méth.* and the *Diction. Class. d'Hist. Nat.*; to the *Règne Animal*, t. v. pp. 316–32, and more particularly to M. Van der Linden's *Observations sur les Hyménoptères d'Europe de la Famille des Fouisseurs.*

[5] From διπλόος, *double*, and πτερα, *wings*, in reference to the *folding* of these organs.

[6] The character however is not universal,—the genus *Ceramius*, Lat. of which Klug has published a monograph, forming an exception.

The larvæ of these insects are without feet, and each is enclosed in a cell where it is fed, according to its kind, either on the bodies of insects carried thither by the mother at the period of oviposition, or on the nectar of flowers, the juices of fruits and of animal matter, elaborated in the stomach of the parent, or in that of the workers, and carefully supplied from day to day. This tribe corresponds to the genus *Vespa* of Linn.

The genus CERAMIUS of Lat. differs from all the others in having the superior wings stretched or extended, and in the amount of the cubital cells, of which there are only two. The labial palpi are moreover longer than those of the maxillæ. The species occur in South Africa, and the warmer regions of Europe.[1]

In all the following genera the superior wings are folded, and present three complete cubital cells.

Sometimes the mandibles are much longer than broad, and approximate anteriorly in the form of a rostrum. The ligula is narrow and elongate. The clypeus is nearly heart-shaped or oval, with the point anterior, and more or less truncate. All the species are solitary, and each is composed of only males and females. The latter provision their young both before their birth and during the continuance of the larva state. Their nests are usually formed of earth, and are either concealed in the holes of walls, beneath the ground, in old wood, or are external, and placed on plants. Each nest contains a supply of caterpillars or other larvæ, which the female piles up in a circular form. She sometimes also stores up spiders, which she has the precaution previously to pierce with her sting.

In the genus SYNAGRIS, Lat. the ligula is divided into four long plumose filaments, without glandular points at their extremity. The mandibles of some of the males are very large. The species are few in number, and characteristic of Africa. In EUMENES, Lat. the ligula is divided into three portions, glandular at their extremity. The abdomen in some is ovoid or conical, and thicker at the base. Such are PTEROCHILE of Klug, remarkable for the great length of the labium and maxillæ, and for their labial palpi beset with long hairs, and composed of only three distinct articulations. In ODYNERUS, Lat. those parts of the mouth are much shorter, the labial palpi are nearly smooth, and consist of four perceptible divisions. *Vespa muraria* of Linn. belongs to this genus. It is described by Réaumur.[2] The female perforates deep holes in sand, or in the plaster of walls, at the orifice of which she forms an outer tube, at first straight, afterwards recurved, and composed of an earthy paste, arranged in thick contorted threads. In the cavity of the interior cell she heaps up from eight to twelve little green larvæ of the same age, disposing them in beds one above another, in a circular form. After depositing her egg, she closes the mouth of the hole, and destroys the outward scaffolding. The abdomen in others has its first segment narrow and elongated in the form of a pear, and the second bell-shaped. Such is the genus EUMENES proper, of which *E. coarctata*, Fab. constructs a spherical nest of fine earth on the stems of plants. She fills it with honey, according to Geoffroy, and then deposits an egg.

Sometimes the mandibles, scarcely longer than wide, have a broad oblique truncation at their extremity. The ligula is short, or but slightly elongated. The clypeus is almost square. These insects constitute the genus VESPA, or wasps properly so called. They unite in numerous associations, composed of males, females, and neuters. The last two kinds detach particles of old wood or bark with their mandibles, reduce and moisten them to the consistence of a paste resembling paper or pasteboard in its nature, and construct nests containing horizontal combs suspended from above by one or more pedicles; on the inferior side there is a range of vertical cells in the form of hexagonal and truncated pyramids. These cells serve solely as lodgings for the isolated larvæ and nymphs. The amount of combs forming the same nest varies; and the nest itself is sometimes open or exposed, sometimes surrounded by an envelope, pierced by a common and almost always central opening, which corresponds with a string of holes for the purposes of internal communication, if the edges of the combs adhere to the inner side of the external covering. These singular constructions are sometimes suspended to the branches of plants in the open air, sometimes concealed beneath the earth or in the hollows of old trees. Their form likewise varies according to the species.

The females commence their labours in spring, and in the first place in a state of solitude. In a nest of small dimensions they deposit the eggs of neuters or workers, which, as soon as they are hatched and attain maturity, enlarge the dwelling, and assist in rearing additional members of the body politic. For a considerable time the society consists only of the original founder of the colony, that is, the female parent, and of neuters. Towards the end of summer or beginning of autumn, young males are hatched, along with additional females. But all such larvæ and nymphs as have not completed their final metamorphosis before the month of November are murdered by the neuters, and torn from their cells. These destroyers are themselves ere long destroyed, in common with the males, by the first frosts of winter. The latter sex never work. A few females alone survive the rigours of the winter season, and these again, on the return of spring, become each the founder of a new but equally transitory empire. Of the death and desolation which is so soon to overtake their busy race, the *genus irritabile* is, however, all unconscious during the glad summer days, or those of the *fruitful* autumn, in which they ply their never-ceasing labours:—

> So fails, so languishes, grows dim, and dies,
> All that this world is proud of;

and hymenopterous and human kingdoms, alike decay and perish. The polity of wasps, we may observe, is not so exclusively monarchical as that of bees. It partakes rather of the republican order, as many females dwell together in amity during the autumnal season. These Vespæ are almost omnivorous. They prey on other insects, on flesh and fruits of every kind, especially when ripe and sweet. They appear to an uninstructed eye as very gluttonous; but their apparent greed becomes more excusable, when we consider that they are catering, not for themselves, but for a numerous and otherwise unprovided offspring. The larvæ, in consequence of the peculiar position of the opening of their cells, lie in a reversed position, with their heads downwards. When about to pass into the nympha state, they shut up their cells, and fabricate a cocoon.

In several species, that portion of the inner margin of the mandibles which is beyond the angle, and terminates it, is shorter than that which precedes the angle. The central part of the front of the clypeus is pointed. These belong to the genus POLISTES of Lat. and Fab. in which we class *P. morio* from Cayenne. Its nest is large, in the form of a truncated cone, pierced inferiorly and at one side. It is composed of very thick pasteboard. Here also are placed the *Vespa gallica* of Linn. and the *V. nidulans* of Fab. *P. Lecheguana*[1] is a species which we owe to M. Aug. St Hilaire, who brought it from the interior of Brazil. Its combs contain an excellent honey, resembling in consistence that of our own domestic species, but possessing at times the singular quality of rendering those who eat it furious, or void of reason. It has been known from ancient times that common honey is occasionally possessed of very deleterious properties, arising probably from the nature or condition of the flowers from which it is collected. The naturalist just named, and two men by whom he was accompanied, nearly perished in consequence of eating of the Brazilian honey in its poisonous state.

---

[1] See Klug's *Entomologische Monographien*, p. 219, et seq.

[2] *Mémoires*, vi. xxxvi. 1–10.

In other wasps the superior portion of the inner margin of the mandibles, or that which succeeds the angle, is as long if not longer than the other portion of that margin. The central part of the front of the clypeus is widely truncated. The abdomen is always ovoid or conical. These constitute the genus VESPA properly so called, of Latreille. The French entomologist here places the *V. crabro*, Linn., which we call the *hornet*. (Plate CCXXXII. fig. 18.) It builds its nest in sheltered places, such as barns, old walls, wooden posts, and hollow trees. It is of a roundish shape, composed of coarse materials, and resembles an old leaf in colour. This species devours other insects, and robs bees of their honey. Though a well-known English insect, it has not yet been found in Scotland. The common wasp, *V. vulgaris* (ibid. fig. 19), forms a somewhat similar nest; but it is composed of finer paper, contains a greater number of combs, and is sheltered in a hole in the earth. *V. media*, Lat. is intermediate as to size between the two preceding. It hangs its paper dwelling beneath the branch of a bush or tree. The nest of *V. holsatica*, Fab. is worthy of a brief record. It is almost globular, pierced at the top, and enclosed beneath in a kind of saucer. It is sometimes observed abroad, in barns, or attached to the beams of garrets, and has even been found in hives. It is not unknown in Britain.

FAMILY IV.—ANTHOPHILA,[2] LAT.

In this, the last family of the stinging Hymenoptera, we find a peculiar power existing in the two posterior legs,—that of collecting the pollen of flowers.[3] This character distinguishes our present groups from those of every other family of insects. The first articulation of the tarsi of the hinder legs is very large, compressed, and in the form of a square pallet, or of a reversed triangle. The maxillæ and the labium are usually very long, and constitute a kind of trunk. The ligula is generally shaped like the head of a lance, or resembles a lengthened filament, of which the extremity is silken or hairy. The larvæ are fed exclusively on honey, or the fecundating pollen of flowers. The perfect insects restrict their own diet to the nectareous juices of flowers, and (when Flora's kingdom has fallen before the approach of winter) to the secretion which they form from these, which we call honey. These Hymenoptera, embracing the great genus APIS of Linnæus, are divided by Latreille into two sections.

SECTION 1ST, ANDRENETÆ, Lat.

The genera of this section have the intermediate division of the ligula heart-shaped or lance-shaped, shorter than the sheath, and bent upwards in some, almost straight in others. They correspond to the *Pro-abeilles* of Réaumur and Degeer, the Andrenæ of Fabricius, and the Melittæ of Kirby.[4]

The Andrenetæ are solitary insects, and consist of only males and females. Their mandibles are simple, or terminated at most by two dentations. The labial palpi resemble the maxillary, and the latter have six articulations. The ligula is divided into three portions, of which the lateral are short, and in the form of auricles. The majority of the females collect the pollen of plants by means of the hairs of their hinder legs, and mixing it with a little honey they thus form a paste for the nourishment of their young. They form holes in the ground, frequently even in firmly-trodden places by the sides of roads, or in fields, and of considerable depth. In these they place their paste, and depositing an egg along with it, they close up the entrance with earth.

Some have the middle division of the ligula widened at the extremity, almost heart-shaped, and doubled in repose. Such is the genus HYLÆUS, Fab. which is now partitioned into two. In the first, or HYLÆUS properly so called (Plate CCXXXII. fig. 20), the body is smooth, the second and third joints of the antennæ of almost equal length, and the upper wings present only two complete cubital cells. The species being hairless, do not collect pollen, and seem to deposit their eggs in the nests of other Hymenoptera of this family. In the second genus, COLLETES, Lat. the body is hairy, the third article of the antennæ exceeds the second in length, and the upper wings present three complete cubital cells. The females collect their stores from flowers. Such is the *Apis succincta* of Linn.—"l'abeille dont le nid est fait d'espèces de membranes soyeuses," of Réaumur.[5] The male is distinguishable by his more lengthened antennæ. The female forms in the earth a cylindrical hole, of which the walls are endued with a gummy liquid, which has been compared to the viscous and shining slime left by slugs on the places over which they have passed. She then forms a number of thimble-shaped cells, apparently composed of the same material, placed end to end, and in a string, and each containing an egg and a suitable portion of paste.

Other Andrenetæ are distinguished from the preceding by the form of the ligula, which is lanceolate. In some of these, that part is folded on the superior side of the sheath, as in the genera ANDRENA and DASYPODA of Lat. (Plate CCXXXII. fig. 21). The females of the latter have the first joint of the tarsi very long, beset with lengthened hairs after the manner of a little feather. The upper wings in both these genera have only two cubital cells. The *Andrena flessæ* of Panzer, common in the environs of Paris, secretes a peculiar kind of honey, black and oily like the grease (cambois) used for carriage-wheels. It has a narcotic odour. In others the ligula is straight, or slightly bent underwards at its extremity. Such are the genera SPHECODES, HALICTUS, and NOMIA, of Latreille.

SECTION 2D, APIARIÆ, Lat.

In this second section of the honey-making Hymenoptera the genera are characterized by the middle division of the ligula being at least as long as the mentum or its tubular sheath, and setiform or filamentary. The maxillæ and labium are greatly elongated, and form a sort of trunk, geniculate and bent beneath while not in action. The two first articulations of the labial palpi have generally the form of a scaly and compressed seta, which embraces the sides of the ligula; the two others are very small, and the third is usually inserted near the exterior extremity of the preceding, which terminates in a point.

---

[1] *Ann. des Sciences Nat.* t. iv. p. 339.

[2] From ανθος, *flower*, and φιλος, *lover*.

[3] Latreille remarks that the parasitical species are not possessed of this faculty;—but the form of their legs is essentially the same, those parts being merely destitute of the hairs or brushes.

[4] *Monographia Apum Angliæ.*

[5] *Mémoires*, vi. xii.

The Apiariæ are either solitary, or united in society.

A.

In the former, which constitute the first principal division, the species consist of only two kinds of individuals, of the ordinary nature of male and female. Each female provides, by her own unassisted efforts, for the preservation of her posterity. The posterior legs are unprovided with the silky down (la brosse) on the inner face of the first articulation of the tarsi; neither do we perceive that particular depression on the outer side of the tibiæ, which the French naturalists distinguish as *la corbeille*, or the basket, and which is so useful in the economy of the *workers* in certain other genera. That outer side, as well as the corresponding part of the first articulation of the tarsi, is usually furnished with numerous close-set hairs.

a.

The first subdivision of these solitary Apiariæ consists of species in which the second articulation of the posterior tarsi of the females is inserted in the centre of the extremity of the preceding one; the exterior and terminal angle of the latter does not appear dilated or more advanced than the interior.

*

We shall first signalise a group of genera which have been named *Andrenoides*, no doubt from the resemblance which they bear to the latest of the preceding genera in their labial palpi, composed of slender linear joints, placed end to end, almost entirely similar to those of the maxillary palpi, and which are six in number. The labrum is always short. The females have no brush on the abdomen; but their posterior legs are clothed or garnished with tufts of hair, which serve them to collect the pollen of flowers. Some have the mandibles narrow, contracted towards the extremity, terminated in a point, and, in common with the labrum, smooth. Such are the genera Systropha, Illig. Rophites, Spinola, and Panurgus, Panzer. Others have the mandibles, in the females, almost spoon-shaped, very obtuse, carinated or grooved, and bidentated at the end. The labrum is very hard, and ciliated above. The antennæ are strongly geniculate and filiform. The upper wings have three complete cubital cells, the first intersected by a little transparent line, the second triangular, the third the largest, and receiving the two recurrent nervures. The genus Xylocopa, Lat. (Plate CCXXXII. fig. 22), resemble large humble-bees. Their body is usually black, sometimes covered in part with a yellow down, and the wings are frequently adorned by brilliant tints of violet, copper, and green. The males of several species differ greatly from the females. Their eyes are large, and more approximated superiorly. Their anterior legs are dilated and ciliated. The species figured, which is the *Apis violacea*, Linn. is one of the best known in European countries. The female excavates holes in old wood, divided into several cells, in each of which she deposits an egg, and a portion of paste for the sustenance of the future grub. The species are very numerous in foreign countries, and seem to spread over many regions of the globe. Comparatively few occur in Europe.

* *

In other genera the labial palpi appear under the form of scaly setæ; the first two articulations are very large, or much lengthened, compared to the last two, of a scaly consistence, with the margins membranous or transparent. The maxillary palpi are always very short, and have not unfrequently fewer than six articulations. The labrum in a great number is lengthened, inclined upon the mandibles, sometimes in the form of an elongated square, sometimes of a lengthened triangle.

The group named *Dasygastræ* by Latreille are remarkable, as their name implies, in this, that the abdomen of the female is almost always furnished with numerous short, close-set hairs, which form as it were a silky brush. The labrum is as long or longer than broad, and of a square form. The mandibles of the females are strong, incisive, triangular, and toothed. The paraglossæ are always very short, in the form of scales, pointed at the end. Of all the genera which compose this group, that called Ceratina approaches most closely to that of which we last figured an example; and, according to Maximilian Spinola, the habits of the females are identical with those of the Xylocopæ.[1] We have several species in Britain. All the remaining *Dasygastræ* have at most only four articulations to the maxillary palpi, and two complete cubital cells. In the six genera next ensuing, the abdomen is obviously furnished beneath with a silky brush. The species belonging to Chelostoma, Lat. and Heriades, Spin. form their habitations in the hollows of ancient trees. In the genus Megachile, Lat. the maxillary palpi are composed of only two articulations, the abdomen is plain above, and susceptible of being raised upwards,—thereby enabling the female to use her sting over her body. This genus contains several singular insects, of which the habits have been well described by Réaumur and other observers.[2] *M. muraria* is one of the largest of the genus. The female is black, with dark wings tinted with violet; the male is covered with reddish hairs, the terminal segments of the abdomen being black. The former sex constructs her little nest on walls and stones in sunny places. It is made of fine earth worked into a kind of mortar, which drying, becomes very hard and durable. On this account the term *mason-bee* is applied to this insect, and to several other species of analogous habits. The interior of these nests contains about a dozen cells, in each of which the provident parent deposits an egg and a piece of paste. The perfect insect is not produced till the spring of the ensuing year. Another species, *M. sicula*, Lat. is black and hairy, with the front, the upper part of the thorax, and the legs, bright yellow. The female constructs a hard and spherical nest, of rather more than an inch in diameter, which she attaches to the branches of heath and other plants. This insect occurs both in Egypt and the south of Europe, and was lately noticed in Corsica by M. Payraudeau. The habits of other species of the genus Megachile are very different from those just noted. They are known by the name of *leaf-eating bees* (Plate CCXXXII. fig. 23), on account of their employing in the construction of their nests perfectly oval or circular pieces of leaves, which they cut out with the most remarkable dexterity. These pieces are conveyed to their straight cylindrical holes, which they previously excavate in the earth, or sometimes in walls, or the decayed trunk of an old tree. They line the bottom of the cavity with these cuttings, and form a thimble-shaped cell (ibid. fig. 27), in which they deposit the honeyed provision on which the larva is destined to feed. After laying an egg, they close the cell by means of a flattish or slightly concave lid, also formed of a portion of leaf. These little cells are repeated one over the other till the hole is filled up. To this division of the genus belongs the *M. du rosier* of Lat. (*Apis centuncularis*, Linn.). The genus Lithurgus, Lat. is furnished with four articulations to the maxillary palpi, and the abdomen is depressed above. All the articulations of the labial palpi are placed end to end. The females have a rounded projection in the middle of the head. Such are *Centris cornuta*, Fab. and an unpublished species from the Isle of France, alluded to by Latreille. In the genus OSMIA of Panzer the maxillary palpi consist of four articulations, or at least of three very distinct ones, and the abdomen is convex above. The habits of the species have been observed by Réaumur, Degeer, Spinola, and other naturalists. Several are *masons*, and have frequently two or three horns on the clypeus, which are probably of use in the construction of their nests. These are concealed in the earth, in chinks of walls, door-posts, and old wood, and sometimes even in the shells of snails (*Helices*). One of the most interesting of the genus is the *Osmia papaveris*, which lines its subterranean dwelling with the gorgeous petals of the scarlet poppy. Another, *O. gallarum*, takes possession of a fungous gallnut formed by a kind of Cynips which inhabits the oak. The hollow space left by the Cynips being too small, the little bee enlarges it considerably, and polishes the interior. The genus is composed of about thirty species, which seem almost peculiar to Europe. A considerable number occur in Britain. The other genera of this group are ANTHIDIUM, Fab., STELIS, Panzer, and COELIOXYS, Lat.[1] The two last-named genera of Dasygastræ resemble the ensuing group in wanting the silky brush, from which it has been presumed that they also coincide with them in being parasitical; but their labrum is parallelogramic, and the mandibles are triangular and dentated. The maxillary palpi are very short and bi-articulate.

---

[1] See the article *Ceratine*, in the 2d edition of the *Nouv. Dict. d'Hist. Nat.*

[2] *Mémoires*, t. iv.

* * *

A third group of genera in this subdivision of the (solitary) Apiariæ is named *Cuculinæ*. They resemble the preceding in the posterior tarsi, and agree with the concluding genera in the labial palpi being in the form of squamous setæ; they also resemble the genera *Stelis* and *Coelioxys* in the abdomen being destitute of a silky brush. They are parasitical, and their bodies are almost smooth and coloured like those of wasps, sometimes partially clothed or hairy. The labrum assumes the form of a lengthened and truncated triangle, or is short and almost semicircular. The mandibles are narrow, ending in a point, and at most unidentated on the inner side. The paraglossæ are often long, narrow, and setiform. The scutellum in several is emarginate or bidentated; in others it is tubercular. These insects correspond to the *Nomadæ* of Fabricius. Several appear in those countries to which they are indigenous, flitting about in spring partly near the ground, or on walls exposed to sunshine. They are then employed in searching for the nests of other Apiariæ, in which they, cuckoo-like, deposit their eggs. It was in reference to this habit that Latreille named them Cuculinæ. The genera are AMMOBATES, PHILEREMUS, EPEOLUS, Lat., NOMADA, Fab. (Plate CCXXXII. fig. 24), PASITES, Jur., MELECTA, Lat., CROCISA, Jur., OXÆA, Klug.[2] Of these, Nomada is the richest in British species. The genus occurs in Asia, Africa, and America, although the majority are characteristic of, if not peculiar to, Europe. The genus Melecta is not unknown in Britain.

b.

The concluding subdivision of the solitary bees is characterized by the first article of the posterior tarsi being dilated inferiorly on the outer side, so that the following articulation is inserted nearer to the internal angle of its extremity than to the opposite one. The outer side of that first angle, as well as the corresponding part of the tibiæ, is furnished with thick and close-set hairs, forming, especially in several exotic species, a sort of brush or tuft,—and thence the name of *Scopulipedes*, bestowed on this division by Latreille. The under part of the abdomen is naked, or at least unprovided with a silken brush. The number of cubital cells is three, with few exceptions, and each of the last two cells receives a recurrent nervure.

Sometimes the maxillary palpi consist of from four to six articulations.

In a certain number the mandibles exhibit only a single tooth on the inner side. These species fly with great rapidity from flower to flower, and with a buzzing sound. They construct their nests either under ground, or in the clefts of old walls. Several prefer ground which has been cut perpendicularly, and exposed to the sun. Those species in which the two lateral portions of the ligula are as long as the labial palpi, and setaceous, and of which the antennæ of the males are lengthened, form the genus *Eucera* properly so called (Plate CCXXXII. fig. 25). The male of a British species (*Apis longicornis*, Linn.) is black, with the labrum and the anterior extremity of the head yellow; its upper portion, thorax, and two first segments of the abdomen, are covered by a reddish down. The female (at one time described by Fabricius as a distinct species, under the name of *Apis tuberculata*) has short antennæ. The maxilla and labium form at their base a slight projection. The abdomen is marked by grey stripes, with a reddish termination. Several other species occur in Britain. Spinola has detached certain species, of which the maxillary palpi have only five distinct articulations, and the superior wings only two cubital cells. These he names MACROCERA.[3] The MELIPODES of Lat. may be defined as American Euceræ, with but four joints to the maxillary palpi, and three cubital cells to the superior wings. In the other Apiariæ of this subdivision, the paraglossæ are much shorter than the ligula, and always exhibit three cubital cells. In MELITTURGA and ANTHOPHORA, Lat. (of both of which several species are indigenous to Britain), the maxillary palpi have six articulations. In SAROPODA, Lat., likewise known among ourselves, the maxillary palpi have only five articulations, and those of the labium are continuous. Lastly, in the genus ANCYLOSCELIS, Lat., of which the species are native to Brazil, the maxillary palpi offer only four articulations.

In others the mandibles have several dentations on the inner side, and the maxillary palpi, as in the preceding genus, have four articulations. Such is the American genus CENTRIS of Fab.

Sometimes the maxillary palpi consist of only a single very small articulation, which even becomes imperceptible in certain species. The paraglossæ are very short, and the mandibles dentated. Such are the genera EPICHARIS and ACANTHOPUS of Klug.[4]

B.

Our second principal division of the Apiariæ is constituted by many interesting insects, such as the garden and humble bees, so remarkable for their peculiar *regime*, and the gregarious habits of the species, each of which consists of three kinds of individuals—males, females, and neuters, as the workers are often called. The posterior tibiæ of these last named are furnished on their external face with a smooth depression called the basket, in which they place the pollen collected from flowers by means of the silky down or brush with which the inner face of the first joint of the posterior tarsi is provided. The maxillary palpi are very small, and consist of a single articulation. The antennæ are geniculate.

---

[1] See *Règne Animal*, t. v. p. 350.

[2] For the characters of the above genera, see *Règne Animal*, t. v. p. 352–3; and Kirby's *Monographia Apum Angliæ*. The haunts and habits of the species are noted under their generic titles in the *Encyclop. Méth.*, and the *Diction. Class. d'Hist. Nat.*

[3] The name is objectionable, either on Spinola's part or Meigen's (according to whoever used it last),—as we observe that the German author, in his *Zweiflügeligen Insecten*, applies the same title to a dipterous genus.

[4] See *Encyclop. Méth.* and other works already named.

Sometimes the posterior tibiæ are terminated by two spines, as in the genus Euglossa, Lat. (Plate CCXXXII. fig. 26), which has the labrum square, and the false proboscis, or prolonged parts of the mouth, as long as the body. The labial palpi terminate in a point formed by the two other articulations. The species are peculiar to South America. Latreille supposes that we owe to the one which we have here figured (*E. dentata*), and to that called *E. cordata*, the green honey so much esteemed in the Antilles. We are still ignorant of the habits of these insects. In the genus Bombus (ibid. fig. 29), the species of which we recognise in this country as *humble-bees*, the labrum is transverse, and the proboscis obviously shorter than the body. The second articulation of the labial palpi terminates in a point, bearing the two others on its outer side. There are few associations of our childhood more deep and lasting than those connected with the pursuit and capture of these beautiful creatures, some of which are remarkable for their size, and the rich contrast which they exhibit of velvet black and crimson, with bars of brilliant yellow. This splendid attire, however, saves them not from being rudely handled; and we remember the day when an artificial *bink*, that is, a little box made of clay, with a piece of glass at one end, and a sprinkling of sugar at the other, contained as many captives in proportion to its size, as the black-hole of Calcutta. But the practice of *blobbing* was one we never patronized, although we know it is pursued in this country, just as it seems to be, judging from the following quotation, by the youth of the *Great Nation*:—“Ils sont bien connus des enfans, qui les privent souvent de la vie pour avoir le miel renfermé dans leur corps, et le sucer.[1] The exciteable genius of a great English poet is roused to a wider range of sentiment and association by the sight of one of these industrious beings.

And is she brought within the power
Of vision?—o'er this tempting flower
Hovering until the petals stay
Her flight, and take its voice away!
Observe each wing—a tiny van!—
The structure of her laden thigh,
How fragile!—yet of ancestry
Mysteriously remote and high,
High as the imperial front of man,
The roseate bloom on woman's cheek;
The soaring eagle's curved beak;
The white plumes of the floating swan;
Old as the tiger's paw, the lion's mane
Ere shaken by that mood of stern disdain,
At which the desert trembles.—Humming-Bee!
Thy sting was needless then, perchance unknown;
The seeds of malice were not sown;
All creatures met in peace, from fierceness free,
And no pride blended with their dignity.
—Tears had not broken from their source,
Nor anguish strayed from her Tartarian den;
The golden years maintained a course
Not undiversified, tho' smooth and even;
We were not mocked with glimpse and shadow, then
Bright seraphs mixed familiarly with men,
And earth and stars composed a universal heaven.[2]

Be this as it may, the species of the genus Bombus inhabit subterranean dwellings, assembled together in social groups amounting to from fifty to sixty individuals, or even in certain cases to between two and three hundred. These unions, however, differ from those of the honey or garden-bee in this, that they are dissolved, like those of wasps, on the approach of winter. They consist of *males*, distinguished by the smallness of their size, their feebler heads, their narrower mandibles, terminated by two dentations, and bearded, as well as by their frequent difference of colour; of *females*, which are larger than the other individuals, and have spoon-shaped mandibles; and of *workers*, of which the mandibles are likewise spoon-shaped, and the size intermediate between the two preceding kinds. Of these workers, Réaumur was the first to distinguish two varieties,—one comparatively large and strong, the other smaller, but more lively and active. This curious fact was afterwards verified by Huber the younger. According to the observations of the Genevese observer, several of the workers born in spring couple during the month of June with males sprung from a common mother, and soon afterwards deposit eggs, from which, however, males alone are produced. These latter couple with the females which are born towards the end of the season, and which continuing through the winter in a pregnant state, become each the founder of a colony in spring. In the mean time, all the others perish, without excepting even the smaller females. The workers, then, though, in common with those of the garden-bee, often called neuters, are in fact females, but of smaller size than the more regular mothers, and with the productive faculty imperfectly developed. No sooner has the genial influence of spring penetrated the mossy cells where these more ponderous matrons have enjoyed their winter sleep, than they rouse themselves from their repose, and wing their dubious flight in search of the first opening crocus, or other garden flower; or, if remote from man, and destined to boom amid wild uplands or other pastoral wastes, the flowering *saughs* (*Salix caprea*), which so often skirt the edges of our mountain streams, and beautify the crystal waters by the reflection of their golden blossoms, afford them a sufficing food. The lover of nature knows how, even among sterile solitudes, a few bright sunny days call into life and beauty many fragrant flowers, not long unvisited by these glad labourers, who ere long settle in some fit abode, and lay the foundations of a future city.

The nests of humble-bees are generally formed beneath the earth, and at a depth of one or two feet. Dry plains, fields, sloping banks, and the sides of hills, are their common localities. These subterranean cavities are of considerable extent, wider than high, and in the form of a dome. The ceiling is constructed of earth and carded moss, carried thither fibre by fibre. The inner walls are plastered over by a coating of coarse wax. Sometimes a simple opening serves as a passage to the foot of the nest; sometimes a tortuous road, of one or two feet in length, leads to the habitation. The bottom of the cavity is lined with a layer of leaves, for the reception of the brood. The female first places in it masses of brown irregular wax, called *pâtée* by Réaumur, and compared to truffles by that naturalist, on account of their shape and colour. Their cavities are destined to contain the eggs and larvæ. The latter live together in society until such time as they are ready to assume the nympha state; they then separate and spin ovoid silken cocoons, vertically fixed against each other. The nymph is always found in a reversed position, or with the head downwards, like those of the females of the honey-bee; and the cocoons are uniformly pierced at their lower end when the perfect insect escapes from its prison. Réaumur asserted that the larvæ fed upon the wax which formed the walls of their habitations; but these, according to M. Huber, merely serve as a protection from cold and moisture; and the actual food consists of an ample provision of pollen moistened with honey, which the labourers provide for the helpless objects of their instinctive affection. When the supply is exhausted, they pierce the cover of the cells, put in an additional supply, and re-close the protecting habitation. We may truly observe, in relation to these delightful labours, that it is not alone in the "great waters" that man may behold the wonderful works of an omnipotent Creator; for literally the *earth* is "full of his goodness." These affectionate labourers, so pervaded by the instincts of maternity, though themselves for the most part barren, watch like rejoicing mothers over the destiny of the future citizens; and as soon as they perceive that a generous diet has increased their dimensions, they enlarge the size of their habitations. We find moreover in these nests three or four small bodies resembling goblets, composed of brown wax, or of the same consistence as the *pâtée*, always open, and more or less filled with good honey. The exact situation in the hive of these honey jars is by no means constant. It has been said that the workers make use of the empty cocoons for the same purpose; but their doing so is deemed very doubtful by Latreille, in as far as these cocoons are not only formed of a silky substance, but are perforated on the under side.

---

[1] *Règne Animal*, t. v. p. 357.

[2] Wordsworth's *Vernal Ode.*

The larvæ are hatched in about five days after the deposition of the eggs, and accomplish their metamorphoses in the months of May and June. It was formerly supposed that labourers alone were produced at this period; but we have already alluded to the simultaneous production of a certain number of males. The labourers immediately proceed to assist the female founder in her operations; and from this period the number of cells which serve as habitations for the larvæ and nymphs is greatly augmented. They form irregular combs, rising in stages, on the edges of which the pâtée of Réaumur is particularly observable. According to Huber, the workers are extremely greedy of the eggs of the female, and sometimes in her absence open the cells in which they are deposited, in order to suck the milky fluid they contain! a most extraordinary fact, as Latreille observes, and one which seems to belie the noted attachment which they entertain for the germs of that race of which they are the natural and appointed guardians. The wax secreted by humble-bees is elaborated by the same peculiar process as that which produces the more beautiful material with which the garden species constructs its honeyed cells. It in fact results from honey, transuded through the intervals of the rings of the abdomen.[1] Several females dwell together in unity, and do not exhibit that instinctive aversion towards each other so remarkable among our domesticated species.

Yet these bees, however humble, have enemies, numerous and of various kinds. Their habitations are uprooted or otherwise attacked by foxes, badgers, weasels, polecats, rats, field-mice, ants, and moths. Certain *Volucellæ* (*Syrphi* of Fab.) deposit their eggs in their nests, the larvæ proceeding from which devour the eggs of the legal occupants. The larvæ of a species of *Conops*, described by MM. Lachat and Audouin, live, like intestinal worms or the grubs of Strepsiptera, within the abdomen of the perfect bee; and after acquiring wings, they make their escape from between the segments.[2]

The species of the genus Bombus are extremely numerous, and seem extended over almost all the regions of the earth. "Scarcely any genus of the insect creation," observes Mr Kirby, "has so large a range as this of *Bombus*. It is found in the old world and in the new; and from the limits of phænogamous vegetation to the equator; but its metropolis appears to be within the temperate zone."[3] We cannot here enter into descriptive details. In Great Britain alone we have above forty different kinds. Of these, the *B. muscorum* (*Apis muscorum*, Linn.), called *Foggie* by the Scottish schoolboy, is recognisable by its reddish colour, uniform in the males, females, and neuters. In *B. lapidarius* the female is black, the abdomen with a red termination; the male (which is the *B. arbustorum* of Fab.) has the front of the head and both ends of the thorax yellow,—the abdomen having likewise a red extremity. This species differs from the others in its habit of forming its nest under stones. Hence its Latin trivial name. The *B. terrestris* is a very common and very beautiful species, widely distributed. It is black, with the posterior extremity of the thorax and the base of the abdomen yellow. The termination of the latter part is white. The *B. arcticus* of Kirby is black, with the base and apex of the thorax, and the anterior half of the abdomen, pale yellow. This insect is the *Apis alpina* of Otho Fabricius;[4] but not the species so called by Linnæus, which the former author supposed it to be. "The insect before us," says Mr Kirby, "differs so slightly from the description which O. Fabricius has given of that which he mistook for the *Apis alpina* of Linné, that there can be little or no doubt of their identity. He confesses that his specimens (and this bee appears to have abounded in West Greenland, as it was also observed to do in Melville Island, and wherever the expedition landed within the arctic circle) did not in all things agree with the characters assigned to that species. But he states, that as Linné had seen only a single specimen, he did not think himself at liberty to make a new species on account of an insignificant difference. Although, however, Linné had seen this bee only once, it has since been more frequently taken; and having received specimens of it from Sweden, through the kindness of Major Gyllenhal, which agree with the Linnæan description in every point but size (a circumstance easily explained, by supposing the original specimen a queen and those sent to me neuters), I can venture to assert that the two insects are perfectly distinct. *Bombus alpinus* is entirely black, with the upper side of the abdomen, all but the base, covered with orange-coloured or ferruginous hairs. The antennæ also of the female or neuter (an important distinction in a genus the species of which are usually only distinguished by the colour of their hirsuties) are proportionally shorter; and the short hairs that cover the tarsi are black."[5] The range of the true *B. arcticus* seems limited by the arctic circle, and extends from Greenland only in a westerly direction,—at least the species does not appear to have been observed in Lapland, Iceland,[6] or other eastern portions of that chilly zone. A European species, named *B. Lapponicus*, is said to be well known in North America, and to extend as far north as Nova Scotia.[7] Dr Richardson, the intrepid arctic traveller, informed the author of the present treatise, that in the course of the northern land expedition he saw some bees in very high latitudes, resembling our common humble-bee (*B. terrestris?*), but that he did not at the time ascertain the precise species; and the circumstances under which he was then placed unfortunately prevented his preserving specimens of the softer kinds of insects.[8]

[8] For a detailed history of the genus Bombus, the reader may consult, in addition to the works already named, "Observations on several species of the genus Apis, known by the name of Humble-Bees, and called Bombinatrices by Linnæus," by Mr P. Huber, in *Linn. Trans.* vol. vi. p. 214.

The remainder of our social Apiariæ are not characterized, like the preceding, by spines at the extremity of their posterior tibiæ. They form two genera.

In the genus **Apis**, Lat., or honey-bees *par excellence*, the workers have the first articulation of the posterior tarsi in the form of a lengthened square, and furnished on its interior face with a silky down, or divided into transverse or striated bands. We here place our invaluable garden species *Apis mellifica*, Linn. (of which we have represented the worker, the female, and the drone, on Plate CCXXXII. figs. 28, 30, and 31), on the wonderful history and attributes of which we could dilate with pleasure to ourselves, if not with satisfaction to our readers, had not the subject been already here treated of at length, and by an abler hand.[1] We shall merely here remark, that all the species of the genus Apis properly so called are peculiar to the ancient countries of the world, and that the domestic culture of the honey-bee is of an origin so remote as to be lost in the depth of ages. It served among the Egyptians as the hieroglyphical emblem of royalty, and has been more or less attended to by all civilized nations of whom we have any record; for innumerable in all but the darkest times are the writers who have told—

> Of treasure suck'd from buds and bells,
> For the pure keeping of those waxen cells,
> Where she, a statist prudent to confer
> Upon the public weal, a warrior bold,
> Radiant all over with unburnished gold,
> And armed with living spear for mortal fight,
> A cunning forager
> That spreads no waste,—a social builder, one
> In whom all busy offices unite,
> With all fine functions that afford delight,
> Safe through the winter storm in quiet dwells!

Our honey-bee (*A. mellifica*), though now well known in America, is in that country not an indigenous, but an imported species. Our land expeditions did not observe its occurrence to the north of Canada. The Americans have now *settled* the Missouri, as far as the 95th meridian; and it is probable that the New England men, in their journey westward, carried hives along with them. According to Mr Warden, the hive-bee was not found to the westward of the Mississippi prior to the year 1797; but it is now well known, and has been so for a considerable time, as high up the Missouri as the Maka nation,—having proceeded westward six hundred miles in fourteen years.[2] Such a distance seems great for these tiny creatures to advance by the ordinary process of swarming, even supposing that the flight of the new colonies was invariably in a western direction. It is at the rate of forty-three miles a year; but they have perhaps been smitten by the Yankee passion for settling beyond the clearings.[3]

Besides the species above named, various other honey-bees are found in different regions of the earth. The *Apis unicolor* of Lat. occurs in Madagascar and the Isle of France, and yields an esteemed honey of a green colour, like that of the Antilles. The *Apis Indica* of Fab. is found in Bengal and at Pondicherry. The *Apis fasciata* of Lat. is domesticated in Egypt, and is carried at certain seasons, for the sake of a double harvest, from Lower into Upper Egypt, just as we transport our own species, when the "flower-enamelled meads" are on the wane, to the blooming heather of the mountain solitudes. The *Apis Adansonii* is a species found in Senegal; and the *Apis Peronii* is native to the island of Timor, from whence it was first brought by the enterprising navigator whose name it bears. In relation to the European kinds, we have no other British species than the one so frequent in our garden-hives; but the Italians cultivate with success the *Apis Ligustica* of Spinola, which is by some entomologists supposed to occur in the wild state, and unimported, in the Morea and the Mediterranean Archipelago.[4]

The terminal genus of the social bees (and with it we conclude the hymenopterous order) is that called **Melipona** by Illiger and Latreille. It is distinguished from the preceding genus by the form of the first articulation of the posterior tarsi, which is narrower at the base, or in the shape of a reversed triangle, and without striæ on the silky brush of its interior face. The upper wings have only two complete cubital cells, while there are three in the genus Apis. These Hymenoptera inhabit South America, and build their nests, which resemble bagpipes, on the tops of trees, or in their cavities. Their honey is extremely sweet and agreeable, but very liquid, and apt to corrupt. The Indians form from it a favourite spirituous liquor. These details apply to *M. amalthea*, of which M. Cordier possesses a specimen enclosed in amber. The species in general have been observed by many travellers, but by few naturalists; and it is therefore not very easy to refer the recorded observations on their history to the proper species. Some nearly allied insects form the genus **Trigones** of Lat.[5]

ORDER VI.—LEPIDOPTERA, LINN.[6]

This splendid and much-admired order is characterized by the possession of four membranous and veined wings, covered by close-set scales, which frequently present the most brilliant and richly varied colours. The mouth consists of lengthened filaments or threads, the union of which forms an extensile spiral trunk or tongue, with which the nectareous juices of flowers are absorbed. Two palpi (corresponding to the labial palpi of masticating insects), consisting of three articulations, act as a sheath or guard on either side of the tongue when rolled up. The superior or maxillary palpi are usually very small, inconspicuous, or obsolete. The chrysalis is *obtected*, that is, covered over or

---

[1] See the article Bee of this work, vol. iv. p. 518. We shall merely observe, in regard to the conversion of the neuter or working bee into a queen-mother, that a great degree of obscurity seems still to pervade the writings of all entomologists, whenever that singular subject is touched upon. Nothing in the history of these creatures has been more clearly demonstrated than the fact of such conversion,—but how a change of food should operate in the course of a few days a determinate change in the organic form and instinctive character of an insect, is as yet a mystery. We are more willing to believe than competent to understand several of M. Huber's facts. It is easy to conceive a greater development of particular organs, the germs of which previously existed,—but the positive alteration in the structure of the feet and maxillæ is not so readily accounted for. We still require some more precise and detailed information regarding this mysterious transmutation than the observations even of the Hubers have furnished. It would tend greatly to elucidate the subject if a series of comparisons could be made at different periods of their development, between the larvæ, nymphs, and perfect insects of the two kinds of queen-bees,—namely, those which were deposited originally in the royal cells (the legitimates), and those whose condition has been altered by the bees themselves in consequence of a failure in the royal line (the citizen-queens). It has not yet been ascertained at what periods or in what manner these singular changes of form take place, further than that the common maggot or bee-worm, on which the change is to be effected, must not exceed the age of three days.

Lepidoptera.

concealed by a crustaceous envelope, which however exhibits to a certain extent the external traces of the limbs, thorax, and abdomen.

The Lepidoptera are the most beautiful of all insects, and exhibit in their colouring every imaginable hue. It is not the mere brilliancy of the broader masses of colour, or their gorgeous combination, which alone delights our eyes, —but the exquisitely varied markings by which the hand of nature has traced her enigmatical characters on the "sail broad vans" of these fairy and fantastic creatures. What are the forms

> Painted on rich men's floors for one feast night,

or the most elaborate Mosaic pavement, when compared with the imbricated surface of a butterfly's wing![1] It was probably the highly ornamental nature of this order that induced Degeer and Olivier to place it at the head of the class of insects.

The mouth of the Lepidoptera does not differ essentially in its structure from the same organ in the masticating or mandibulated orders.[2] Savigny and Latreille have shown, in a manner at once precise and philosophical, that it is composed of the same pieces, and that these pieces are peculiarly appropriated to the functions which they are required to perform; thus some parts of little use exist in a merely rudimentary condition, while others of a more indispensable nature have gained an increase of development. The component parts are: a labrum, often nearly invisible, conical, or subulated; two corneous mandibles, very small, rudimentary, hairy, or garnished with small scales, and fixed, or apparently useless; two corneous maxillæ, in the form of tubular threads, generally much extended, and soldered together as far as the origin of the palpi, and forming by the union of their inner edges the trunk or sucker, of which the interior presents three canals; two maxillary palpi, often almost imperceptible, consisting of from one to three articulations, and inserted near the bend of the maxillæ; two labial or inferior palpi of three articulations, closely set with hairs or scales, and rising on each side of the trunk, of which they form a kind of sheath. The labium is composed of a single piece, flat, and triangular.

The antennæ vary in the different groups, but they are always composed of a great number of articulations. In the diurnal tribes they are simple, and generally terminated by a small inflation or knob; in the crepuscular they assume the form of an elongated or fusiform mass; in the nocturnal they are filiform or setaceous, whether pectinated or simple, and often plumose, especially in the males. In many species we find a pair of stemmatic eyes concealed among the scales, and placed between the ordinary eyes or organs of vision. The latter are hemispherical, of considerable size, and composed of innumerable facettes. The trunk is either ineffective or altogether wanting in some of the crepuscular and nocturnal tribes. The three segments of which the thorax of many other hexapod insects is visibly composed, seem here united into one,—the anterior being very short and transversal, as in the hymenopterous and dipterous orders. The form of the thorax is extremely uniform, and any apparent variety of aspect is caused chiefly by the extension of its hairy or scaly covering, which sometimes assumes the shape of a crest. The abdomen is composed of from six to seven segments. It is attached to the thorax by a very small portion of its diameter, and never offers either sting or ovipositor, although in a few females (as in *Cossus*) the terminal rings are narrow, and lengthened into the form of a pointed and retractile oviduct. The scales of the wings, on which their gorgeous beauty depends, are implanted by means of a small pedicle. Their figure is variable. They are usually somewhat elongated, rounded at the base from the side of the pedicle, and truncated at the outer extremity, which is generally toothed or serrated. The under wings frequently form on their inner margins a kind of canal for the reception of the abdomen. Among many of the diurnal kinds, the four wings, in a state of repose, are raised perpendicularly, so as to meet above the back; in the two other great sections they are horizontal or inclined; and in these there is often a strong spine or bristle on the anterior margin of the inferior wings, which being received by a buckle-like process of the under surface of the superior pair, maintains them in their position.

The legs of the Lepidoptera are as usual six in number, and the tarsi are composed of five articulations, and are terminated by a pair of hooks. In several diurnal genera the anterior pair are much shorter than the others, are useless as locomotive organs, and are folded on the sides of the chest; their tarsi being large, indistinctly articulated, and destitute of apparent hooks. The existence of the sense of smell in the class of insects is clearly demonstrated by the habits of many species of this order. The males of many nocturnal Lepidoptera discover the females of their own kind at a great distance, even when the latter are carefully and intentionally concealed from sight. The female is generally for the most part perceptibly, and in many instances considerably, larger than the males. They deposit their eggs, by an admirable and wisely granted instinct, not on the plants which they themselves affect during their first buoyant courses, but on such as are best adapted for the future nourishment of their crawling and wingless offspring.

The larvæ of Lepidoptera, usually known under the name of Caterpillars, are composed of twelve annular segments, exclusive of the head. They are furnished with nine stigmatic openings on each side, and the three anterior segments of the body are respectively furnished with a pair of short legs of a scaly consistence, terminated by a hook, and corresponding to the true legs of the perfect insect. There are, besides, from four to ten membranous or false feet upon the other segments. The body of caterpillars is generally elongated, soft, almost cylindrical, and frequently adorned by bright or beautiful colours, besides being variously provided with spines, hairs, or tubercles. Many are however naked, or unprotected by any other than a cutaneous covering. The head is harder than the other parts, and is covered by a corneous or scaly skin. It presents on each side six small shining grains, which are regarded as simple or stemmatic eyes; and two very short conical antennæ are likewise perceptible. The mouth is composed of two strong mandibles, a pair of maxillæ, a labium, and four palpi. The food of caterpillars consisting not of vegetable juices alone, but of the actual substance of the leaves and roots, and even of the well-matured woody fibres of timber trees, the masticating organs are beautifully adapted to their functions. But no sooner is the creeping and voracious larva about to transform itself into the "angelic butterfly," which floats on gaudy

---

pinions from flower to flower, and sustains itself only on the most ethereal of their nectareous juices, than the parts of the mouth undergo a change not less remarkable than that of the general form and aspect, and the long tubular proboscis above described is developed, in subservience to the habits of a new existence. The change, however, is by no means sudden or immediate, but is effected through the transitionary state of chrysalis, of which we have already said perhaps more than enough in our attempted exposition of the mysteries of transformation. We cannot, however, here avoid to notice the elaboration of that silky substance which, towards the termination of the caterpillar's career, becomes so singular a feature in its natural economy, and one of such vast importance in the artificial *habits* of the human race. It is formed in two long tortuous interior vessels, which, becoming gradually more slender at their upper extremities, terminate in a small conical spinner at the end of the labium. Had these insignificant secreting organs not existed in the silk-worm, or other allied species, what a difference of character would have been manifested in the lustrous aspect of baronial halls, and even of the courts of kings! It is curious, indeed, to consider how the breeding of a few millions of caterpillars should occasion such a disparity at different times in the circumstances of different tribes of the human race. When the wife and empress of Aurelian was refused a garment of silk, on account of its extreme costliness, the most ordinary classes of the Chinese were clad in that material from top to toe; and although among ourselves week-day and holiday are now alike profaned by uncouth forms, whose vast circumference is clothed "in silk attire," yet our own James the Sixth was forced to borrow a pair of silken hose from the Earl of Mar, that his state and bearing might be more effective in the presence of the ambassador of England,—"for ye would not, sure," said the royal pedant, "that your king should appear as a scrub before strangers."[1] King Henry the Eighth was the first of the English sovereigns who wore silk stockings.

Many caterpillars, in walking, fix the anterior feet on the plane of their position, and, bending their body upwards, they advance and fix their anal feet, assuming for a time the form of a loop. They then unfix their anterior hold, and stretching forward their bodies, proceed as it were by spanning the ground. They are hence called surveyors (*arpenteuses*) by the French naturalists. Others, known under the name of *Batons*, fix themselves, in repose, to twigs and branches by their hinder feet, and thus hold themselves out stiff and immoveable for many successive hours. It may easily be supposed that this extraordinary attitude must require the exercise of, comparatively speaking, most enormous strength. No vertebrated animal, not in a state of catalepsy, could sustain it even for a few seconds. We find accordingly (through the laborious investigations of a great interpreter of nature, Lyonnet) that even in the caterpillar of *Cossus ligniperda*, a species which lives in trees, but does not exercise itself in the way alluded to, there are above 4000 muscles. Many move along the ground rapidly by the successive motion of each segment, as if a wave were flowing over or pervading their bodies. The intestines of caterpillars consist of a large canal without inflections, the anterior portion being sometimes slightly separated in the form of a stomach, and the posterior forming a wrinkled cloaca. There are also four very long biliary vessels, usually inserted pretty far back.

The habits of caterpillars are very various in the different kinds. Although a great majority feed on vegetable substances, many of the smaller kinds are extremely destructive among stuffed birds, and all kinds of woollens. They will even devour leather, lard, wax, wafers, and all fatty matters. Many confine themselves to one particular substance, while others are polyphagous. Some unite in society, and form a silken tent to screen themselves from their natural enemies, and the extremes of heat and cold; others are independent and solitary. As they increase in size they cast their skins, and this process of sloughing generally takes place about four times. A great proportion, before assuming the chrysalis state, spin around them a web or cocoon, more or less compact according to their kind. In some (as in *Bombyx mori*, or the silk-worm) it is of a rich saffron colour, and of exquisite fineness; in others it is of a membranous texture, from being originally more compactly glutinous, instead of consisting of distinct threads. Many mingle with their funeral web or winding-sheet, particles of earth or decayed vegetable substances, which greatly increase the size of their cocoons. The chrysalids of the diurnal Lepidoptera are, however, naked or exposed, and are usually suspended by the posterior extremity, or fastened by a silken cord or girth around the middle of the body. They are also angular in their forms, while those of moths are rounded or cylindrical. In one or two of the crepuscular kinds, or Sphingides, the proboscis projects, and is encircled by a separate envelope, even in the chrysalis state. All the other parts are, however, swathed in a coriaceous covering, although the form of the wings and other members may be traced externally, in slight though distinct relief. The abdominal segments are capable of motion, like the "thews and sinews" of a warrior in plaited mail. The period of repose varies from a few weeks to one or two years. Such as assume the chrysalis state late in autumn, do not appear in the winged condition till the ensuing spring. Many remain in the egg state all winter; and such diurnal Lepidoptera as have two *flights* in the year are generally produced in the first place in spring from chrysalids which have lain torpid all winter, and become themselves the parents of another flight, which make their appearance at a later period of the same season. Thousands perish before attaining the perfect state, not only as the natural food of most passerine birds, but as the living bed of the Ichneumonides, which deposit their eggs in the fatty substance of the caterpillar, and thus by degrees deprive it of the source of life.

The observance of these and of other singularities, which we cannot here detail, will afford a never-failing source of interest to the student of nature's mysteries, and will assuredly yield an ampler and more enduring recompense than "Pyrrhos' maze or Epicurus' stye." In spite, however, of all that has been said and written of the wonders of entomology (and the subject, to be understood, must rather be seen than listened to, or even reflected on through the pages of the best instructed author), we fear that many continue to regard it with very inadequate notions. But how may not piety itself revolt at the thought of the most numerous works of an Almighty Creator's hand being regarded as trifling or unworthy of a deep and most reverential consideration. When Solomon, whose earthly glory never equalled the lustre of the "lilies of the field," desired us to ponder on a meet emblem of diligence and wisdom, it was not from what we consider as the most important parts of the creation that he drew his example:—"Go to the *ant*, thou sluggard; consider *her* ways, and be wise." So spake, and under a divine impulse, he who is himself emphatically called the "wisest of men." Yet in many a high-

Lepidoptera Diurna.

flown moral and (pseudo) religious declamation, folly and ignorance not seldom combine to illustrate whatever is mean, insignificant, or worthless, by a reference to some unfortunate form of insect life. Even the pious Newton (not Sir Isaac, but the author of *Cardiphonia*, whose name was John) somewhere likens the extremest act of thoughtlessness and folly to a person breaking off from some worldly and important presence to "pursue a butterfly." Did the excellent author forget, or never know, that a butterfly is not only in itself a creature of such exquisite beauty that neither the "sea of light," nor any other of the most famous gems which ever from the brow of an eastern tyrant dazzled the dark eye of a trembling slave, can compare with it in varied and gorgeous lustre;—or did he expunge from his recollection that the same divine hand which formed man after his own likeness, also created every other thing which breathes the breath of life, and that all were declared *good* when seen by that eye, before whose brightness even the angels veil their faces? Compared with the eternal interests of man, we admit that all earthly pursuits, including even the best and purest—those of science—are as dust in the balance; but, bearing in mind our higher destiny, and yet believing that as there are celestial bodies and bodies terrestrial, so we cannot be better occupied than in devoting a convenient season to study (without which we cannot understand) the works of God,—for "the glory of the celestial is one, and the glory of the terrestrial is another," and both, though differing from each other in brightness, co-exist in divinest harmony, simply because

> The hand that made them is itself divine.

Therefore, though ourselves among the most loyal of liege subjects, we should not hesitate to pursue a butterfly, if wanting to our collection, "even in the presence of a crowned king." But this, we fear, is a digression.

In lepidopterous insects in the perfect state, we find a first lateral stomach or crop,—a second, inflated or turgid,—a small intestine, tolerably long,—and a cæcum near the cloaca.

The order is naturally divisible into three families, viz. Diurna, Crepuscularia, and Nocturna.

FAMILY I.—DIURNA.

The insects of this family, commonly called Butterflies, are never seen on the wing except during the day, and in a state of repose usually hold their wings erect. Their antennæ are capitated, or terminated by a club or knob, with a few exceptions, such as the splendid genus *Morpho*, in which they are almost filiform, and the Fabrician genus *Urania*, in which they become more slender towards their extremities. The caterpillars have always sixteen feet, and the chrysalids are naked and angular. These are the only lepidopterous insects in which we never find the exterior margin of the inferior wings presenting a rigid seta or bristle, for the retention of the superior pair.

The genus Papilio of Linnæus, divided into certain sections, contained the whole of that splendid and infinitely-varied tribe which we call Butterflies, of which the species are so numerous and diversified that naturalists soon felt the necessity of multiplying the genera, both because it was right so to do, and for the mere convenience of restricting the amount of species contained in each. In the later editions of the *Systema Naturæ*, Butterflies, or diurnal Lepidoptera, were divided into six phalanges. The first, called *Equites* (which now correspond to the true genus *Papilio*, as restricted by Latreille), was divided into *Troes* and *Achivi*, a division since ascertained to be rather unfortunate in some respects, in as far as it occasionally separates the males and females of the same species; the second was named *Heliconii;* the third *Parnassii;* the fourth *Danai*, subdivided into *Candidi* and *Festivi;* the fifth *Nymphales*, also subdivided into *Gemmati* and *Phalerati;* the sixth *Plebeii*, again divided into *Rurales* and *Urbicolæ*. Geoffroy (in his *Histoire abregée des Insectes*) follows the Linnæan system, and improves it chiefly by applying the principles previously established by Réaumur in his *Mémoires*. Degeer and Olivier likewise so far follow Linnæus as to retain the name *Papilio* as a generic term; but, in order to facilitate the labours of the student, they have introduced additional sections and subdivisions. The labours of Scopoli, as we have elsewhere observed,[1] are defective in relation to these insects, in consequence of his generic characters being drawn from the presence or absence of spots on the wings, and other distinctions which are of little or no value, except for the formation of artificial sections, or the discrimination of species. In the earlier works of Fabricius, scarcely any alterations were made in the arrangement of the Linnæan *Papiliones*. But in the *Entomologia Systematica* of that author, and still more in his *Systema Glossata* (left unfinished at the period of his death, a great number of genera were eventually created.[2] Latreille, in his numerous works, has constituted various generic groups, which appear to have been very generally adopted. Of the chief of these we shall speedily give account. Denis and Schiffermuller (in the *Catalogue des Lepidoptères de Vienne*) had previously benefited this branch of Entomology, by assuming the form and metamorphosis of the caterpillar as principal bases of their divisions; and Ochsenheimer has since successfully applied the same method to all the European species. Our ignorance of the history of the greater proportion of exotic groups has unfortunately retarded the more general application of the principles of an improved system, although Dr Horsfield's admirable *Lepidoptera Javanica* has done much to complete our knowledge of many fine Javanese species. Dumeril and Lamarck have also, each after his own manner, endeavoured to amend the classification of diurnal Lepidoptera; and in regard to pictorial works in this department, Clerk, Cramer, Engramelle, Hubner, Ernst, Esper, Stoll, Herbst, Jablonsky, Godart, and others, have published collections of coloured figures, some of which stand unrivalled in extent and magnificence by the most costly productions of those who have most successfully endeavoured to illustrate any of the kindred branches of natural science. Even in our own country, where natural history is so sparingly patronised, and so lightly valued, this beautiful branch of zoology has been rather sumptuously exhibited, and the names of Drury, Abbot, Wilkes, Shaw, Donovan, Lewin, Leach, Swainson, Stephens, Curtis, and Horsfield, will readily occur to the grateful recollection of the reader.

Indeed, on account of the exquisite beauty of their forms and colours, Butterflies have, from the earliest periods of natural history, greatly excited the zeal and admiration of collectors. They occur in all quarters of the world,—from the frozen shores of Greenland and Spitzbergen, to high southern latitudes; but the tropical regions of Asia and America are the most productive of large and splendidly-coloured species.

---

[1] *Illustrations of Zoology*, letter-press preceding plate xxviii.

[2] Illiger has given an extract from the last-named work, in his *Magazin;* and the English reader will find it exhibited by J. G. Children, Esq. in the *Phil. Mag. and Annals* for February 1830.

M. Latreille divides the Linnæan Papiliones into two sections.

SECTION 1ST,

Contains all those butterflies which have but a single pair of spurs or spines to their tibiæ, and placed at the posterior extremity of these parts. When in a state of repose they raise their wings perpendicularly, joining them at the tips. Their antennæ are usually clubbed or inflated at the extremity, sometimes almost filiform. In this section are included the genus Papilio and the Hesperiæ *ruricolæ* of Fabricius. It is itself divisible as follows.

*

Third joint of the inferior palpi sometimes almost wanting, sometimes very distinct, but equally well clothed with scales as that which precedes it. Hooks of the tarsi apparent or projecting.

Some of the genera of this subdivision are hexapod or six-footed, that is, all the feet are formed for walking, and are almost identical in both sexes. Their chrysalids, in addition to the common attachment by the posterior extremity, are fixed by the passing of a silken thread across the body. A few are enclosed in a rude cocoon. The central cell of the lower wing is closed inferiorly.

In PAPILIO (proper) of Latreille (Plate CCXXXIII. fig. 2), the inferior palpi are extremely short, scarcely reaching the clypeus with their upper extremity; their third joint is indistinct. The species of this genus are remarkable both for elegance of shape and beauty of colouring. Those spotted with red on the breast form the division of *Eguites Troes* of Linn.; those destitute of such marks he styled *Achivi* or Greeks. They abound in the tropical countries of both hemispheres, but are rare in more northern countries. Indeed we are not aware that more than three exist in Europe, viz. *P. Machaon*, *Podalirius*, and *Alexanor*, of which the first is a well-known native of some of the southern counties of England. The caterpillars of this genus are naked, and when alarmed protrude from the superior part of the neck a soft forked horn, that usually diffuses a penetrating and unpleasant odour. The chrysalis is exposed, and is supported by means of a silken band. In the genus PARNASSIUS of Lat. (*Doritis*, Fab.), Plate CCXXXIII. fig. 3, the inferior palpi evidently extend above the clypeus, taper to a point, and are distinctly triarticulated. The terminal button of the antennæ is short, almost ovoid and straight. The females are provided with a kind of corneous boat-shaped sack at the posterior extremity of the abdomen. The species of this interesting genus seem peculiar to the alpine or subalpine countries of Europe and the north of Asia. Their caterpillars possess a retractile tentaculum, like those of the preceding genus; but they form, prior to their transformation, a cocoon of leaves united by filaments of silk. The species which we have figured in the present work is a noted Swiss insect, *P. Apollo*. It inhabits alpine valleys. It is said, however, to occur on plains near Upsal, and other northern countries. In the genus THAIS of Fab. (Plate CCXXXIII. fig. 5), the palpi resemble those of the preceding, but the terminal button of the antennæ is elongated and curved, and there is no corneous pouch at the extremity of the abdomen of the female. The species are characteristic of the south of Europe. A few occur on mountains. In the preceding genera the internal margin of the under wings is concave or folded. In the two following the inferior wings project beneath the abdomen, and form a canal for its reception. The caterpillars, many of which feed on the Cruciferæ, have no tentaculum. The species correspond to the *Danai candidi* of Linn. and include all our common white Butterflies. In PIERIS, Lat. (*Pontia* of Fabricius and of the English entomologists), Plate CCXXXIII. fig. 6, the inferior palpi are almost cylindrical and slightly compressed, with the last articulation at least almost as long as the preceding. The club of the antennæ is ovoid. We have nine or ten British species, including what are usually called cabbage-butterflies, such as *P. brassicæ*, *napi*, &c.; also the more richly attired Orange Tip, or Lady of the Woods, *P. cardamines*.[1] Mr Stephens confines the generic title of *Pieris* to the hawthorn butterfly, *P. cratægi*, a species as yet unknown in Scotland. In the genus COLIAS of Fab. (Plate CCXXXIII. fig. 4), the club of the antennæ forms an elongated and reversed cone, and the inferior palpi are greatly compressed, with the last joint much shorter than that which precedes it. The indigenous species are in general more warmly coloured than those of the preceding genus.

Lepidoptera Diurna.

Other genera of this subdivision (*Tetrapoda*) have the anterior pair of feet much shorter than the others, folded on the breast, and unfit for walking; sometimes in both sexes, sometimes only in the males. The chrysalis is simply attached by its posterior extremity, and hangs with its head downwards. The genus DANAIS (*Euplœa*, Fab.), part of the *Danai festivi* of Linn. (Plate CCXXXIII. fig. 4), are distinguished by their triangular wings, and antennæ terminated by a kind of elongated and curved button. In IDEA, Fab. the wings are almost oval and elongated, and the antennæ nearly filiform. In HELICONIUS, Lat. (*P. Heliconii*, Linn.) (Plate CCXXXIII. fig. 7), the antennæ are twice the length of the head and thorax, and increase insensibly towards the extremity. In ACRÆA, Fab. the antennæ are shorter, and terminate in a more abrupt button. Those in which the inferior palpi are but slightly compressed, distant throughout their length, or at least at their extremity, and terminated abruptly by a slender and acicular joint, and in which the under surface of the wings is frequently ornamented by silvery spots, or by yellow ones upon a fulvous ground, form the genera CETOSIA and ARGYNNIS (Plate CCXXXIV. fig. 2) of Fabricius and Latreille. The caterpillars (ibid. fig. 3) are beset with spines or tubercles. In the former, of which several species have the wings elevated and elongated, the inferior palpi are distant throughout their entire length, the hooks of the tarsi are simple, and the club of the antennæ oblong. In the latter the club is short and abrupt, the hooks of the tarsi are unidentated, and the inferior palpi are distant only at their extremity. The inferior wings are often rounded. These butterflies are remarkable for the silvery spots upon their under surface. They are called *Fritillaries* by the English collectors. There are four or five indigenous species. The caterpillars have a pair of spines upon the neck, longer than the rest. Such as fall under the genus *Melitæa* of Fab. have yellow spots on the under surface, and the general markings above are more disposed in squares, like a chess-board. In *M. Seleni* and *Euphrosyne*, however, the upper surface is very similar to that of the preceding species, and there is an appearance of pearly or silvery lustre on the under surface of the lower wings. Latreille, we think wisely, unites the whole under the genus ARGYNNIS.

In the five following genera the inferior palpi are contiguous in their whole length, terminate gradually in a point, and are much compressed. The genus VANESSA (Plate CCXXXIII. fig. 9, and CCXXXIV. fig. 1) differs from the others in the antennæ, which are terminated abruptly by a short turbinated or ovoid button. The caterpillars are densely spinous (Plate CCXXXIII. fig. 10). Here is placed the common tortoise-shell (known in Scotland as the

---

[1] For the indigenous species, see *Naturalist's Magazine*, vol. ii. p. 224.

Devil's Butterfly), *V. urticæ*, and several other British species, such as the Camberwell Beauty, *V. Antiopa*, and the Peacock Eye, *V. Io* (ibid. fig. 9). The Painted Lady, *V. cardui*, remarkable for the vast extent of its geographical distribution, being fully more widely dispersed than any other form of animal life with which we are acquainted, belongs to our present genus. It is, however, placed in the genus CYNTHIA by Mr Stephens. In the four following genera the antennæ terminate in an elongated club, or are almost filiform. In LIBYTHIA of Fab. the males alone have the anterior pair of feet extremely short, and tippet-like. The inferior palpi project observably in the manner of a beak. The upper wings are very angular. In BIBLIS, Fab. the palpi are also longer than the head, but more obtuse, and curved a little at their extremity. The anterior legs are abbreviated in both sexes, and the antennæ terminate in a much smaller club. The nerves of the superior wings seem strongly inflated at their origin. In NYMPHALIS, Lat. (Plate CCXXXIV. figs. 5, 7, 9), the legs resemble those of the preceding, but the inferior palpi are shorter. The club of the antennæ is more elongated than in Vanessa, from which they are not strongly distinguished. Their caterpillars are, however, different (ibid. fig. 4), being less spiny, and more elongated towards the posterior extremity, which is slightly forked. The species of this genus (of which, as a British example, we may name the Purple Emperor, placed in the genus APATURA by Mr Stephens) are frequently ornamented by brilliant and varied colours, and, when in prime condition, are highly prized by collectors. They are distinguished by the strength and thickness of their wings, which enable them to exercise a smooth, powerful, and sustained flight. Their motions are consequently not of that zigzag nature observable in many species, but steady and continuous, like the soaring of a bird of prey. They frequently haunt the summits of forest trees, and other elevated stations, and are therefore difficult to capture. This disadvantage, however, is to a certain extent obviated by the boldness of their disposition; for, when their situation is accessible, they are not deterred by an unsuccessful attack from settling again on the spot where they were first observed. The European species, such as the Purple Emperor above named (*N. Iris*), are taken by means of bag-nets, fixed to poles thirty feet high. They are said to be attracted by the odour of acrid or fermenting substances, and such are sometimes used by entomologists to induce them to descend from their inaccessible positions. The genus is very extensive. M. Godart[1] describes 267 different kinds. *Nymphalis Jasius*, the species which we have selected for illustration on the plate last referred to (figs. 7 and 9), is one of the most beautiful of European insects. We received it from M. Case-Nuove of Lyons. The genus MORPHO, Fab. (Plate CCXXXIV. fig. 8), differs from Nymphalis in its almost filiform antennæ, which are feebly and insensibly enlarged towards the extremities, but not clubbed. All the species are peculiar to South America, and are well deserving the special attention of those who desire to form a just notion of the splendour and magnificence of many lepidopterous insects. We could describe them with great pleasure did our limits admit of such details. M. Godart has separated, under the name of PAVONIA (ibid. fig. 10), certain species, of which the central cell of the lower wings is closed, and the most internal nerve of the upper pair is curved in the form of the letter S, in place of being straight or slightly arched. A species found in the East Indies, of which the lower wings are prolonged into a tail (*P. Phidippus*), forms the type of the genus AMATHUSIA of Fabricius. We have figured the larva and chrysalis on Plate CCXXXV. figs. 1 and 8. All the rest belong to the new world. Those which follow have also the discoidal cell of the lower wings closed posteriorly. Such are BRASSOLIS, Fab. (ibid. fig. 3), EUMENIA, Godart (do. fig. 5), EURYBIA, Illiger (do. fig. 10), and SATYRUS, Lat. (do. fig. 6). The caterpillars of the last-named genus are naked, or nearly so, and the posterior extremity of their body is narrowed into a furcated point. The chrysalids are bifid anteriorly, and their back is tuberculated.

* *

> Inferior palpi with three distinct joints, of which the third is almost naked, or much less thickly covered with scales than the preceding ones. The hooks of the tarsi are very small, and scarcely if at all projecting. The discoidal cell of the posterior wings is open posteriorly.

The caterpillars of this subdivision are oval, or resemble *Onisci* in their forms. The chrysalids are short, contracted, smooth, and always fixed, like the genus PAPILIO properly so called, by a silken thread across their bodies. These butterflies were classed by Linnæus among his *Plebei*, in the division of *Ruricolæ*, and Fabricius placed them in a corresponding section of his *Hesperiæ*. They form the genus ARGUS of M. Lamarck, and contain, among other species, all our beautiful little *Blues*, which in bright summer days so enliven our grassy downs, and almost all other spots of open sunshine.

Sometimes the antennæ terminate, as usual, in a small and solid button-like inflation. In the genus ERYCINA, Lat. (Plate CCXXXV. figs. 2 and 4), the anterior pair of feet are much shorter than the others, at least in the males. They belong to America. In the rest all the legs are alike in both sexes. In MYRINA of Fab. (ibid. fig. 11) the inferior palpi are long and projecting. In POLYOMMATUS (ibid. fig. 12) the palpi do not extend much beyond the epistoma. These beautiful little insects receive their name from the number of small eye-like spots with which their under surface is ornamented. We have a considerable amount of indigenous species, most of which are blue above, the females of some being brown. In the Scotch Argus (*P. Artaxerxes*), so common near Edinburgh in June and July, at the base of Arthur's Seat, above the line of the Railway, both sexes are blackish-brown above, with a variable white spot on the disk of the upper wings, and some lunated red spots, more or less distinct, on the under. The splendid little butterflies called *Coppers* are placed by our collectors in the genus LYCÆNA of Fabricius.

A few Lepidoptera of our present subdivision are remarkable for the peculiar form of their antennæ. Those of one of the sexes of the genus BARBICORNIS, Godart, are setaceous and plumy,—those of ZEPHYRIUS, Dalman (Plate CXXXXV. fig. 7), are terminated by ten or twelve globular joints, separated like the beads of a rosary.

SECTION 2D.

The second section of diurnal Lepidoptera contains those species of which the posterior tibiæ are furnished with two pair of spines, viz. a pair at their extremity, and another above. The lower wings are usually retained in a horizontal position, even when the insect is at rest, and the extremity of the antennæ very often forms a distinctly hooked point. Their caterpillars, judging from the few with which we are acquainted, bend together the leaves of plants for a protecting covering, and spin within that leafy chamber an extremely thin cocoon of silk, in which they are transformed into chrysalids. The latter are smooth, and without angular elevations. These Lepidoptera form the *Plebei Urbicolæ* of Linnæus, with the addition, by Latreille, of those rare and splendid insects placed by Fabricius in the genus Urania.

---

[1] *Encyclopédie Méthodique*, art. *Papillon*.

The former belong to the genus Hesperia of Fab. (Plate CCXXXV. fig. 13), and are characterized by the distinctly clavate termination of the antennæ, and by the inferior palpi being short, broad, and thickly covered anteriorly with scales. Here are placed *H. alveolus*, *malvæ*, and *tages* (for chrysalis and larva see fig. 15), among the British species. In the genus Urania of Fab. just alluded to (ibid. figs. 9 and 14), the antennæ, at first filiform, become attenuated or setaceous at the extremity, and the inferior palpi are slender and elongated, with the second article greatly compressed, and the last much more attenuated, almost cylindrical, and naked. "The butterflies," says Mr Swainson, "comprising this remarkable genus, are perhaps the most splendid insects in creation. No art can effectually represent the changeable and resplendent green which relieves the velvet black of the wings, and which varies with every change of light. The typical species are found in Tropical America, where they fly with amazing rapidity, and perform, like their prototypes the swallows, annual migrations. When at rest, the anterior wings are flat or horizontal, but only slightly spread."[1] *U. Leilus* is found in Surinam, and is figured in Madame Merian's work on the insects of that country. *U. Ripheus* of Cramer (*Leilus Orientalis*, Swainson) was originally figured from a specimen taken at Chandernagor, in Bengal, and belonged to the rich cabinet of M. Gigot d'Orcy. We perceive, however, the following notice of its locality in a recent work: "Cette espèce, que l'on peut considerer comme le plus beau Lépidoptère connu, habite *Madagascar*. Elle a été prise une seule fois à Bourbon, où la chenille avoit peut-etre transportée accidentellement."[2] The synonymy of this exquisite insect has been greatly embroiled on account of Cramer supposing the species represented by his figure, which has six tails, to be identical with Drury's, which has none. Mr Swainson has shown that the latter insect, having clavated instead of filiform antennæ, is not only specifically distinct, but pertains to a different genus. He has named it *Rhipheus dasycephalus*.[3] In the *Nouv. Ann.* quoted below, the reader will find an account of the larva of *U. rhipheus*, which, in common with the caterpillars of the other species, has been hitherto unknown to naturalists. Mr Swainson has represented, with his usual elegance and accuracy, almost all the known species of these rare and beautiful insects. That which we have figured in illustration of our present article is a new species (*U. Boisduvalii*), lately published by M. Guerin.[4]

FAMILY II.—CREPUSCULARIA.

The most prominent species of this family are known by the name of Sphinxes or Hawk-moths. They are furnished with a spine or strong bristle on the anterior margin of the inferior wings, which being received by a process of the under surface of the superior pair, maintains them in a horizontal or somewhat inclined position in repose.[5] The character just mentioned is indeed perceptible also among the nocturnal tribes; but our present family is distinguished by the antennæ, which are prismatic or fusiform, usually thickest in the middle. These insects fly with great strength and celerity, owing to the extent and firm consistence of their wings, the powerful muscles by which they are moved, and the bird-like manner in which their taper bodies are poised. From their name, we would naturally infer that they are observed chiefly during the morning and evening twilight; but many species may be seen darting from flower to flower even at mid-day. As their capture is difficult, and their rearing from the caterpillar precarious, they are in general highly prized by collectors. In the larva state they have always sixteen feet. The chrysalis is cylindrical, blunt-headed, with a conical abdomen, and destitute of those points or angular prominences observable in so many of the diurnal Lepidoptera. They are usually enclosed in a cocoon, or concealed either in the earth or under some protecting body. They are supposed to derive the name of *Sphinx* from the peculiar attitude assumed by several of their caterpillars, which in some respects bear a resemblance to the fabled monster of antiquity. A few produce a humming sound. Latreille divides the family into four sections, which, in corresponding order, answer to the genera *Castnia* and *Sphinx* of Fabricius, and to those which he at first named *Sesia* and *Zygæna*.

The first section, named Hesperi-Sphinges, is composed of those species which connect the Hesperides of the preceding family with the Sphinges properly so called. The antennæ are always simple, thickened towards the middle, or at the extremity, which forms a hook, narrowed to a point, without any tuft of scales, at the end. They are all furnished with a distinct proboscis, and the inferior palpi are composed of three very apparent joints.

In the genus Agarista, Leach (Plate CCXXXVI. fig. 1), the inferior palpi are elongated, with the second joint strongly compressed, and the last slender and almost naked; the antennæ are simple, gradually thickened towards the middle, and then becoming attenuated, terminate in an elongated hook. In the genus Coronis, Lat. (ibid. fig. 2), the club of the antennæ is more developed. In the genus Castnia of Fabricius (ibid. fig. 3), all of which are from the new world, the antennæ resemble those of Agarista; but the palpi are shorter, broad, and cylindrical.

The second section, named Sphingides, have the antennæ always terminated by a little flake of scales; the inferior palpi are broad, or transversely compressed, thickly clothed with scales, and the third article generally indistinct. Most of the caterpillars have a smooth body, elongated, thickest towards the posterior extremity, which is furnished with a horn, the sides obliquely or longitudinally striped. They feed on leaves, and undergo their metamorphoses under ground, without spinning a cocoon. Many seem, however, to form a little vaulted chamber, with agglutinated walls, which protects them from the circumjacent earth. Here are arranged many fine insects belonging to the genus Sphinx properly so called (Plate CCXXXVI. figs. 5 and 6), of which the antennæ, from about their centre, form a kind of prismatic mass, either simply ciliated, or transversely striated on one side, in the manner of a rasp. The trunk is very distinct. These insects fly with great velocity, sometimes giving utterance to a humming noise, occasioned no doubt by the rapid vibration of their wings. Instead of settling upon flowers like bees and other insects, they are frequently observed merely to hover over or before them, and to extend their long tubular trunks towards the nectaries. This peculiar motion has probably obtained for them the appellation *hawk-moths*. *S. Atropos*, commonly called the death's-head moth, is one of the finest of the European species. When seized it sometimes utters a shrill cry, caused, according to Réaumur, by the friction of the palpi on the trunk,—in the opinion of M. Lorey, by the escape of air from two cavities in the abdomen. It makes its appearance in the perfect state during autumn. The caterpillar, at least in Britain, feeds voraciously on potato-leaves. It is difficult to rear beyond the chrysalis state. We had six specimens alive at one time during the summer of 1826, all of which entombed themselves after a time beneath the earth, but never made their appearance in the perfect state. On being examined after the lapse of ten or twelve months, they were found lying some inches below the surface, in the state of chrysalis, each in an egg-shaped hollow, formed by the caterpillar. They were quite light and stiff, and of course dead and unproductive of the desired *Imago*. The death's-head moth, in common with several others of the genus, is very widely distributed. We have received it from Africa and the East Indies; and M. Boisduval informs us that it is well known in the Isle of France. The natives of the latter country believe that the dust which it casts from its wings in flying through an apartment, is productive of blindness to the visual organs on which it falls. It is difficult to trace the origin of this fable, recorded by St Pierre in his Voyage to the Isle of France. We have many other native species, which we cannot here enumerate.[1] One of the rarest and most beautiful of the European species, *Sphinx Nerii* (genus *Deilephila*, Ochs.), occurs in Madagascar and the Mauritius. It likewise inhabits Asia Minor, Bengal, and the whole of Africa. We received it from the vicinity of Genoa. It has recently been captured in England.

[3] *Zoological Illustrations*, second series, plate 131.

[4] *Iconographie du Règne Animal*, pl. 82 (*Insectes*).

[5] This character, according to M. Godart, is wanting in some species of the genus *Smerinthus*.

Other genera of the Sphingides have the abdomen terminated by a broad tuft of scales. Such is our humming-bird hawk-moth, *Macroglossa Stellatarum*, Ochs. Some nearly allied species, to which Fabricius latterly applied the generic name of *Sesia* (such as *S. fusiformis*, *Bombyliformis*, &c.), are distinguished by the clear consistence of the greater portion of their wings. In the genus SMERINTHUS of Lat. (Plate CCXXXVI. fig. 11), the antennæ are toothed or serrated.

The third section, named SESIADES by Latreille, contains those species of which the antennæ are always simple, fusiform, and elongated, and frequently terminated, as in the preceding genera, by a little bundle of scales; the inferior palpi are narrow, slender, and distinctly triarticulate, the last tapering to a point. The posterior legs are furnished with very strong spurs. The abdomen is generally terminated by a kind of brush. The caterpillars live by gnawing the interior of the stalks and roots of plants, like those of the nocturnal kinds (such as *Hepialus* and *Cossus*); they are naked, have no posterior horn, and construct, with the debris of the substances on which they are nourished, a cocoon, in which they undergo their final metamorphoses.

In the genus Sesia of Latreille (*Ægeria*, Fab. Plate CCXXXVI. figs. 7, 12, and 13), the antennæ terminate in a little tuft of scales. The wings are horizontal, and composed of clearer vitreous portions, interrupted by darker coloured veins. The posterior extremity of the body is brush-like. Several species exhibit to a casual observer rather the appearance of wasps or flies, than of lepidopterous insects. The genus THYRIS of Hoffmansegg (ibid. fig. 8) resembles Sesia; but the antennæ are more slender, almost setaceous, and without any terminal tuft. The wings are angular and indented. The abdomen terminates in a point. In ÆGOCERA of Lat. (ibid. fig. 9), the antennæ also want the tuft, but they are evidently thickened towards the middle, and fusiform; the second joint of the inferior palpi is furnished with a bundle of hairs, which project in a beak-like fashion. The abdomen likewise terminates in a simple point. The wings are inclined, and entirely covered with scales.

The fourth and final section of our present family is that of the ZYGÆNIDES. It consists of Lepidoptera in which the antennæ, always terminated by a point destitute of a tuft, are sometimes simple in both sexes, fusiform, or resembling the horn of a ram, sometimes thickened towards the middle, almost setaceous, pectinated in both sexes, or at least in the males; the inferior palpi of medium size, or small, nearly cylindrical, and always formed of three distinct articulations. The wings, when at rest, are inclined; that is, sloped down laterally like the roof of a house, and present vitreous spots in many species. The abdomen is not brush-like at the extremity. The spurs of the posterior legs are usually small. The larvæ of these insects live exposed on various Leguminosæ, and other plants. They are short, inflated about the middle, and attenuated towards either end. Their bodies are smooth, or but slightly haired. In the course of their transformations they spin a pretty solid and coriaceous cocoon, attached to the stalk of a plant. The perfect insect issues from the chrysalis in a few weeks. The flight is somewhat heavy, and both sexes may frequently be taken together, reposing on the plants on which the female lays her eggs.

In the genus ZYGÆNA of Lat. (Plate CCXXXVI. figs. 4 and 10), which appears to be as yet unknown in the new world, the antennæ are simple in both sexes, and terminate abruptly in a fusiform mass, or one like a ram's horn. The inferior palpi rise above the clypeus, and are pointed at the end. This genus contains the Burnet moths of the English collectors, of which *L. loti* and *filipendulæ* are well-known examples. The genus SYNTOMIS of Illiger differs from Zygæna chiefly in the antennæ, which are not so thick, but slender, or insensibly fusiform. The inferior palpi are short and obtuse. In the genus ATYCHIA of Hoffm. (ibid. fig. 16), the antennæ are simple in the females, and bipectinated in the males. The inferior palpi are very hairy, and extend obviously beyond the clypeus. The wings are short. The spurs at the extremity of the posterior legs are strong. The genus PROCRIS of Lat. (ibid. fig. 17) approaches the preceding so far as respects the antennæ, but the inferior palpi are shorter and less hairy. An ornamental insect, the *Sphinx Statices* of Linn. affords a good example of this genus. It is called the green forester by Harris, and forms with another species the genus *Ino* of Leach and Stephens. Other Lepidoptera of this section have the antennæ in both sexes bipectinated, or furnished with a double row of elongated teeth. Such of them as have a distinct trunk form the genus GLAUCOPIS of Fab. (ibid. fig. 18)—those in which that organ is wanting or indistinct compose the genus AGLAOPE (ibid. fig. 15).

FAMILY III.—NOCTURNA.

The vast assemblage of species of which this great division is composed, are known under the familiar name of Moths, and correspond to the old and undivided genus *Phalæna* of Linnæus. Their wings, with a few exceptions, are *bridled*, in repose, by means of a bundle of setæ, or the corneous bristle before mentioned in our generalities of the preceding family. Their position is either horizontal or inclined; sometimes they embrace the sides and upper surface of the abdomen. The antennæ are setaceous, or become gradually narrower towards the extremity. They are frequently feathered or pectinated, especially in the males, and are usually more ample in that sex than in the females. The legs of the larvæ vary from ten to sixteen in number. In certain species both sexes seem to want the tongue; and the females of a few have no wings, or but the merest rudiments of those organs. The chrysalids are always rounded, or without angular points.

---

[1] Mr Rennie's *Conspectus of the Butterflies and Moths found in Britain* will prove useful to those who cannot obtain access to the rarer or more costly works from which it is compiled.

These insects, as their family name imports, are seldom seen on the wing till after sunset. They continue their flight, throughout the mild and dewy nights of summer, till the morning twilight. During the brightness of the day season they conceal themselves in tangled vegetation, on the shady side of walls and buildings, on the under side of large leaves, or in the crevices of the gnarled bark of ancient forest-trees, and other sombre places. So astounded indeed are the greater number by the "garish eye of day," that when discovered by the sharp-sighted entomologist, they allow themselves to be taken prisoner without an effort to escape. A few, however, present exceptions to the general rule. Such, for example, are the males of *Bombyx zigzag*, which fly throughout the whole day, and fear not the brightest beams of "glorious Apollo." This same species presents a remarkable confirmation of what we have formerly stated, in the introductory portion of the present article, regarding the sense of smell in insects. The female of the moth just named is extremely sluggish, and seems seldom, if ever, to use her wings. When placed at an open window or elsewhere in an observable position, she will be speedily seen to receive the visits of the males, which fly swiftly towards her from all directions, undoubtedly guided by the sense of smell.

The classification of this family presents great difficulties to the entomologist in the way of a natural division into sections and sub-genera, and to it applies with peculiar force an observation made by Latreille regarding the entire order,—*Lepidopterorum ordo Entomologorum Scopulus.* In fact, the parts of the mouth, from the complex and greatly varied, yet clearly defined structure of which, in the masticating insects, so many excellent and available characters have been deduced, are among the lepidopterous tribes in general restricted in number, simple in form, and very similar in composition. The antennæ, too, especially among the nocturnal tribes, become rather sexual than generic distinctions;—and as the metamorphosis and general habits and history of many of the exotic species, which form the finest features in the richly stored cabinets of Europe, are almost entirely unknown, recourse cannot be had to such excellent and indeed indispensable aids towards a more natural and consistent classification. An accurate, perspicuous, and philosophical arrangement of the Lepidoptera, is therefore still a desideratum in our science.

Latreille, in his latest work (*Règne Animal*, second edition), divides the nocturnal Lepidoptera into *ten* sections. The species of which the wings are entire, or without fissures or digitations, compose the first nine. All those which, under the form of larva, live almost entirely exposed, or in fixed retreats, and of which many have less than sixteen feet, and which in their perfect state are characterized by very small or concealed upper palpi, more or less triangular wings, horizontal or decumbent, and not folding around the body, compose the first eight. The eighth itself is the only one of which the caterpillars have fourteen feet, of which two are anal. If in certain others the same number exists, the anal are wanting.

The first four sections correspond to the divisions *Attacus* and *Bombyx* of the genus Phalæna of Linnæus. The trunk is usually rudimentary or very small, and its two filaments are not united. The inferior palpi, with a few exceptions, are small and almost cylindrical. The antennæ, at least in the males, are pectinated or serrated. The wings are horizontal or decumbent, and in several the lower project, in a state of repose, beyond the upper pair. In some, also, the buckle-like process formerly mentioned as fixing the wings together, is here wanting. The thorax is smooth or uniform, as well as the abdomen, and woolly. The latter portion is for the greater part very voluminous in the females. The cocoon of the chrysalis is generally what may be called well *felted*, and of pretty solid consistence. Although the Nocturna of Latreille's fourth section (*Aposura*) bear a close relation to those which precede them, their caterpillars nevertheless offer a character unique and unexampled in the lepidopterous order,—the absence of the anal feet. We shall here give a brief sketch of the general characters of the nocturnal tribes, in accordance with the system of Latreille.

SECTION 1ST, HEPIALITES.

We may here name as types the genera *Hepialus* and *Cossus* of Fabricius. The caterpillars are rarely met with, as they conceal themselves in the interior of the plants on which they feed. The cocoons which they form are composed in great part of particles of those same plants. The edges of the abdominal rings or segments of the chrysalis are toothed or spinous. The antennæ of the perfect insect are always short, and most generally present only one kind of small, short, rounded, and close-set teeth. Those of some others terminate always in a simple thread, but are furnished inferiorly in the males with a double row of barbs. The trunk is always very short, and not very obvious. The wings are decumbent, and generally elongated. The last rings of the abdomen in the female form a kind of oviduct or tail. In the larva state these insects are very destructive to trees, edible plants, and other useful products of the vegetable kingdom.

Sometimes the antennæ, almost conformable in both sexes, have only very short teeth disposed in one or two rows. Such are the three following genera. In HEPIALUS of Fab. the antennæ are almost granular, and much shorter than the thorax. The under wings are usually destitute of the curb or spine. The caterpillars dwell in the earth, and gnaw the roots of plants (Plate CCXXXVI. fig. 27). A very abundant species, called the Ghost-moth, *H. humuli*, Fab., is characterized by the upper wings of the males being of a silvery white, without spots,—those of the female reddish yellow, with spots of a deeper hue. The larva is extremely destructive to hops, and also exists in great quantities in districts where that useful plant is unknown. It is often seen hovering over churchyards with a short pendulous motion to and fro, and is also frequently observed in pasture-fields, and plots of grass in garden grounds. In the genus COSSUS of Fab. (ibid. fig. 14), the antennæ are at least as long as the thorax, and present on their inner side a range of small lamellar teeth, short and rounded at the end. The caterpillars live in the interior of trees, and make use of the saw-dust produced by the action of their mandibles in the formation of their cocoons. The chrysalids advance by a peculiar and instinctive motion to the external apertures of their ligneous dwellings, just at the moment of their final development, when their wings are about to expand. We doubt not that the little spinous projections with which the sides of the abdomen are armed, aid them greatly in that progressive motion. A wriggling movement would naturally produce an advance upwards or forwards, but retreat would be impossible. The *Cossus ligniperda* is a noted example of the genus. In the larva state (ibid. fig. 19) it is extremely destructive to elm trees, which it perforates almost to the core, and by degrees produces first an unhealthy condition, rendered visible by a peculiar colour of the leaves, and finally decay and death. In the company of an honoured friend, the Rev. John Fleming of Rairigg, Windermere, we lately witnessed the hewing down of an old elm tree, which had braved the blasts of many stern winters, but had evidently become paralysed in its vital functions by the inroads of some insidious foe. By accident the large scaly head of a caterpillar was one day seen protruding from the rugged bark; and some other circumstances led to the belief that the tree was infested. To ascertain the cause of the disease with certainty, and to stay if possible its progress through the neighbouring groves, the sylvan monarch was consigned to the tender mercies of the woodmen of Bowness; and on being felled and hewn in different parts, we discovered several dozens of very large caterpillars of *Cossus ligniperda*, chiefly in the thickest part of the tree, a few feet above the ground, and several inches within the bark. They gave out, as we extracted them, a very peculiar odour, of an oily nature, and sufficiently repelling, we should suppose, to render it improbable that these larvæ were eaten by the ancients. It is however a well-received opinion, that the *Cossus* described by Pliny, and regarded by the Romans as a most delicious fare, was the caterpillar in question. It is frequently found in the willow as well as in the elm, and may possibly extend its ravages to the oak, the nidus assigned by Pliny to his edible worm. The latter, however, was most likely the larva of *Prionus coriarius*, or some other of the larger long-horned beetles; the more especially as we know from Madame Merian and other writers, that the grub of a congener, *Cerambyx damicornis*, is eaten in Surinam and the West Indies, both by slaves and freemen. The perfect insect of the *Cossus ligniperda* is of an ashy grey, with numerous small black lines on the upper wings. The posterior extremity of the thorax is yellowish, with a black line. We forgot to mention, that the oily odour of the caterpillar is by some considered to proceed from a reservoir of a peculiar fluid which the insect disgorges, for the purpose, it is believed, of softening the timber on which it feeds, and in which, as it increases in size, it perforates its hidden chambers. It is also remarkable as having afforded the subject of an extraordinary anatomical investigation by Lyonnet, detailed in his famous *Traité Anatomique de la Chenille du Saule.* The enthusiasm of a French writer has induced him, while lauding the merits of that signal publication, to allude to its subject-matter under the dignifying appellation of "the immortal worm!" The reader may satisfy his curiosity as to its external aspect, by inspecting the 19th figure of our 236th plate. On the same plate, fig. 14, we have represented the winged state of an American species, *C. Macmurtrei* of Boisduval. The genus STYGIA of Draparnaud (ibid. fig. 24), placed by some writers among the *Zygænides*, is ranked by Latreille where we now introduce it. The antennæ have a double row throughout their whole length, of small, short, straight teeth, dilated and rounded at the end.[1]

Sometimes (and this character distinguishes the following genus from those enumerated in the preceding paragraph) the antennæ differ greatly in the sexes; those of the males being furnished inferiorly with a double row of barbs, and terminated by a filament; those of the females being entirely simple, but cottony at the base. Such are the species of the genus ZEUZERA of Lat. (Plate CCXXXVI. fig. 20), of which *Z. æsculi* is a beautiful indigenous example. Its larva dwells in the interior of the sweet chesnut tree, and in that of pear and apple trees. The body of the perfect insect is of a beautiful white, with blue rings on the abdomen, and numerous little spots of the same colour on the upper wings. It is not a common species.

SECTION 2D, BOMBYCITES.

This section may be distinguished, both from that which precedes and that which follows it, by the following characters: The trunk is always very short, and merely rudimentary; the wings are either extended and horizontal, or decumbent, but the inferior wings extend laterally beyond the upper ones; the antennæ of the males are pectinated.

The caterpillars live exposed, and devour the more tender parts of vegetables. They usually spin a cocoon of pure silk. The chrysalids have no spiny processes or dentations on the edges of the rings of the abdomen.

The species with horizontal and extended wings (the Phalænæ Attaci of Linn.) form the genus SATURNIA of Schrank (Plate CCXXXVI. fig. 25), with which Latreille combines AGLIA (*Bombyx tau*) of Ochsenheimer. It comprehends many magnificent species, such as *S. atlas* of China, called *porte-miroir* by the French, on account of the transparent or vitreous portions of the wings. *S. luna*, of a fine and delicate green colour, is an American species, remarkable for the extended tail-like appendages of the under wings.[2] The cocoons of two other species of this division, *Bombyx mylitta* of Fab. and *Phalæna cynthia* of Drury, have been employed for their silk from time immemorial in Bengal. The first of these species appears to be identical with the *Ph. paphia* of Dr Roxburgh. It occurs in great abundance in Bengal, and in many parts of the adjoining country, and affords a plentiful supply of a very durable though coarse and dark-coloured silk called *Tusseh*, much used by the Brahmins and other sects of Hindoos. This species cannot be domesticated; but the hill people go into the jungles, and when they perceive the dung of the caterpillars under a tree, they immediately search for them among the branches, and carry off whatever they require. These they distribute on the asseen trees (*Terminalia alata glabrata* of Roxb.), and as long as they continue in the caterpillar state, the Pariahs guard them from birds by day and from bats by night. The natural food of this species is the *Byer* tree of the Hindoos, called *Rhamnus jujuba* by botanists. The Jaroo cocoons are produced from a mere variety, not a distinct species, of this insect. The Arrindy silk-worm, however, belongs to an entirely different species, the *Phalæna cynthia* above named. It appears peculiar to two districts in the interior of Bengal, viz. Rungpore and Dinagepore, where it is reared in a domestic state. The food of this caterpillar consists entirely of the leaves of the common *Ricinus*, or *Palma Christi*, which the natives call arrindy, and hence the name by which the insect is itself distinguished.[3] The cocoons are in general about two inches in length and three inches in circumference, pointed at either end; they are of a white or yellowish colour, and their texture is extremely soft and delicate. The filament indeed is so remarkably fine, that this silk cannot be wound off, but is spun like cotton. The yarn is wove into a kind of coarse white cloth, of a seemingly loose texture; but of such extreme durability that the life of one person is seldom sufficient to wear out a garment of it, so that the same piece frequently descends from parent to child. It must always be washed in cold water.[1]

---

[1] M. de Villiers has published some new details regarding *S. Australis*, in the *Annales de la Soc. Linn. de Paris*, v. 473. The antennæ in our figure are, we fear, not quite accurately represented, though, from want of a specimen, we cannot correct them. Compare Godart, *Papil. de France*, iii. pl. 22, fig. 29; and Guerin, *Iconog.* (*Insectes*), pl. 85, fig. 4.

[2] This species has been bred at Altona by Mr Zincken von Sommer, from eggs imported from America. We have figured the larva on Plate CCXXXVI. fig. 23.

[3] *Edinburgh Cabinet Library*, British India, vol. iii. p. 155.

The principal European species of the genus Saturnia are known under the names of peacock and emperor moths, &c. such as *S. pavonia major* and *minor*. The former is the largest moth in Europe, and has been known to remain in the chrysalis state for three years.

Other Bombycites have the superior wings decumbent, with the exterior margin of the inferior pair projecting almost horizontally beyond them,—*alæ reversæ*. In the genus LASIOCAMPA (Plate CCXXXVI. fig. 26), the palpi project in the form of a rostrum, and the inferior wings are frequently dentated; some of the species bear a resemblance to little bundles of dried leaves; such are *L. quercifolia* and others. In the genus BOMBYX properly so called (ibid. fig. 21) the inferior palpi exhibit no remarkable projection. Here is placed the famous *Bombyx mori*, or true silk-worm moth, of a whitish colour, with two or three obscure and transverse streaks, and a lunate spot on the superior wings. The caterpillar feeds on the leaves of the mulberry, and spins an oval cocoon of a close tissue of the finest silk, usually of a yellow colour, but sometimes white. A variety is now preferred abroad, which always yields the latter colour. Although this sumptuous product is now "familiar as household words," its nature and origin were but obscurely, if at all, known in ancient times; and even in the days of Aurelian it was valued at its weight in gold. This was probably owing to the mode in which the material was procured by the merchants of Alexandria, who had no direct intercourse with China, the only country in which the silk-worm was at that time reared. According to Latreille, the city of Turfan, in Little Bucharia, was for a long time the rendezvous of the western caravans, and the chief entrepôt of the Chinese silks. It was the metropolis of the Seres of Upper Asia, or of the Serica of Ptolemy, placed, according to that author, between the Ganges and the Eastern Ocean. Hence the *Serica vestis* of the Romans, and the word *Sericum*, their name for silk. Driven from their country by the Huns, the Seres established themselves in Great Bucharia and in India. It was from one of their colonies, Ser-hend (*Ser-indi*), that certain Greek missionaries, in the reign of Justinian, carried the eggs of the silk-worm to Constantinople. Its cultivation spread, at the period of the first Crusades, from the Morea into Sicily, the kingdom of Naples, and, several centuries afterwards, under the administration of Sully more especially, into France, to which country it is now a source of great wealth. Silks were also anciently obtained by sea or land from the kingdoms of Pegu and Ava, or the Oriental Seres, most frequently mentioned in the writings of the earlier geographers.[2] Though the manufactures of silk were lauded in terms of the highest admiration both by Greek and Roman writers, they were in frequent use for some centuries before any certain knowledge appears to have been obtained, either of the precise countries from which the material was derived, or of the mode by which it was produced. By some it was supposed to be a fine down adhering to the leaves of trees or flowers, by others it was regarded as a delicate kind of wool or cotton;[3] and even those who had some idea of its insect origin were incorrectly informed of the natural mode of its formation. The court of the Greek emperors, which surpassed even those of the Asiatic sovereigns in splendour and magnificence, became profuse in its display of this costly luxury; but as the Persians, from the advantages which their local situation gave them over the merchants from the Arabian Gulf, were enabled to supplant them in all those marts of India to which silk was brought by sea from the East, and as they had it in their power to cut off the caravans which travelled by land from China through their own northern provinces, Constantinople thus became dependent on a rival power for an article which its sumptuous nobles deemed essential to the enjoyment of refined life. Of course the Persians, with the usual rapacity of monopolists, raised the price to an exorbitant height, and many attempts were made by Justinian to free his subjects from such exaction. An accidental circumstance is said to have accomplished what the wisdom of the great legislator was unable to achieve. Two Persian monks, who had been employed as missionaries in one of the Christian churches established in India, had penetrated into the country of the Seres, that is, to China, where they observed the natural operations of the silk-worm, and acquired a knowledge of the arts of man in working up its produce into so many rich and costly fabrics. The love of lucre, mingled perhaps with a feeling of indignation that so valuable a branch of commerce should be enjoyed by unbelieving nations, induced them to repair to Constantinople, where they explained to the emperor the true origin of silk, and the various modes by which it was prepared and manufactured. Encouraged by the most liberal promises, they undertook to transport a sufficient supply of these extraordinary worms to Constantinople, which they effected by conveying the eggs in the interior of a hollow cane. They were hatched, it is said, by the heat of a dunghill, and the larvæ were fed with the leaves of wild mulberry.[4] They grew and prospered, worked their webs, underwent their accustomed metamorphosis, and multiplied their kind according to use and wont; and thus, as already intimated, becoming extensively cultivated throughout all the southern countries of our continent, they effected an important change in the commercial relations which had so long existed between Europe and the East.[5]

Another curious species of the genus Bombyx is the processionnary moth, *B. processionnea*, Fab. The caterpillars of this insect live in society on oak trees, where, when young, they spin in common a silken tent, in which they dwell together in unity. They frequently change their domicil until after the third casting of their skins, on which they remain more stationary, forming a new habitation resembling a kind of sack, divided interiorly into several cells. They usually issue forth in the evening, in a very singular order of procession. A single individual takes the lead, and serves as guide, two others follow, forming the second line, then three abreast, next four, and so on for many ensuing columns, each regularly augmented by the addition of a single larva, and all following the course of their first adventurous leader. After a certain time each spins a cocoon alongside that of its neighbour, mingling the hairs of its body with the silken tissue. These hairs, Latreille remarks, are, in common with those of several other kinds, extremely small and fine; and sometimes working their way into the human skin, occasion violent itchings, accompanied by swelling. The inhabitants of Madagascar are known to employ for economical purposes the silk of a caterpillar which likewise dwells in great communities,—a commonwealth of worms. Their nest is sometimes three feet high, and so closely packed with cocoons (500 have been counted in a single mass) that not the smallest hiatus is to be found. The species, however, belongs to the genus *Sericaria* of the ensuing section.

SECTION 3D, PSEUDO-BOMBYCES.

These consist of Lepidoptera in which the inferior wings (in common with those of all the remaining nocturnal tribes) are provided with a curb, which attaches them to the superior when at rest. They are then entirely covered by the latter, and both are decumbent or horizontal, but with the inner edges overlapped (*en recouvrement*, Lat.). The trunk among the concluding members of the section begins to lengthen, and scarcely differs in the final genera from that of other Lepidoptera, except that it is somewhat shorter. The antennæ are entirely pectinated or serrated, at least in the males. The caterpillars live on the exterior parts of vegetation.

Latreille distinguishes first those species in which the trunk is very short, and apparently unadapted to the purposes of suction.

In some, and these are the greater number, the caterpillars live exposed or uncovered, and do not fabricate portable dwellings. Of these, some are elongated, furnished with ordinary feet, well adapted for walking; the rings of the body not soldered above. In the genera SERICARIA of Lat. (Plate CCXXXVI. fig. 22), and NOTODONTA of Ochs. (Plate CCXXXVII. fig. 1), both sexes have well-developed wings. In the former, which contains the *B. dispar* of Fab. so remarkable for the great size of the female, and the difference of her general aspect when compared with the male, the upper wings exhibit no dentations on their inner border. In the latter, which contains *Ph. zigzag* of Linn. that border is dentated. In the genus ORGYIA of Ochs. (ibid. fig. 2), the females are almost apterous (fig. 3), and the caterpillars (fig. 4) are beautifully adorned with aigrettes, or little plumes or tufts of hair. In others of the same tribe the caterpillars creep rather than walk, their feet being extremely short, and even the scaly ones retractile; the body is oval like that of an oniscus, with the skin soldered above from the second ring, so as to form a kind of arch, beneath which the head is withdrawn. These compose the genus LIMACODES, Lat. of which the caterpillars seem to represent, in this section of the Nocturna, those of certain diurnal Lepidootera, such as the genus *Polyommatus*.

Other genera of Pseudo-Bombyces are distinguished from the preceding by the possession of a very distinct trunk, which, when unrolled, extends far beyond the head. The disposition of their colours somewhat resembles that of those diurnal species called chess-boards (*damiers*) by the French. Many of them are extremely rich and beautiful in their adornment. In CHELONIA of Godart (*Arctia*, Schr.) Plate CCXXXVII. fig. 5, the wings are decumbent in repose, the antennæ pectinated in the males, the inferior palpi very hairy, and the trunk short. To this genus belongs that common but superb species commonly called the Tiger-moth (*B. caja*, Fab.). It is produced from the blackish-brown creeping caterpillar usually known in Scotland as " the hairy worm." In CALLIMORPHA, Lat. (ibid. fig. 6), the wings are also decumbent, but the antennæ are at most only ciliated in the males; the inferior palpi are merely covered by little scales, and the trunk is long. *C. Jacobœa* is an ornamental British species, known to our older writers under the names of Pink-underwing, and Cinnabar-moth. The upper wings are brown, with a streak and two spots of carmine. The under pair are carmine, with a blackish border. The caterpillar is hairy and black, and feeds on the flowers of the rag-wort. In LITHOSIA of Fab. the wings are laid as it were horizontally upon the body.

SECTION 4TH, APOSURA, Lat.

The insects of this division are characterized by a peculiarity already alluded to,—the want of feet on the anal segment of the body of the larvæ. They derive their name from that circumstance. The posterior extremity of the body terminates in a point, which in several is forked, or even exhibits two articulated appendages, long and flexile, and forming a kind of tail. The perfect insects differ but little from the preceding in regard to their trunk, palpi, and antennæ. Some, such as DICRANOURA of Godart (Plate CCXXXVII. fig. 7), have the external aspect of Sericaria and Chelonia, with the antennæ of the males terminating in a small simple curved thread. The posterior extremity of the larva is forked (ibid. fig. 8). Others, such as PLATYPTERIX, Lat. bear a great resemblance to the Phalænæ properly so called. Their wings are broad, and the superior angle of the posterior extremity of the anterior pair is somewhat prolonged or falcated. The body is slender. That of the caterpillar terminates in a simple truncated point. In that state they bend over the edges of the leaves of plants, and fix them down by silken cords, so as to form a protecting habitation, which at the same time they partly consume as their natural food. The cocoon of the chrysalis is very bare.

SECTION 5TH, NOCTUÆLITES, Lat.

The species of this extensive section are similar to the preceding insects in the figure and relative proportion of their wings, and their position in repose; but they present the two following distinguishing characters: A horny, spirally rolled, and generally elongated trunk; inferior palpi, terminated abruptly by a very small article, much more slender than that which precedes it,—the latter being broader and compressed. These genera have the body more covered by scales than by a woolly down. Their antennæ are usually simple. The thorax is frequently crested above, and the abdomen assumes the form of an elongated cone. Their flight is rapid, and some of the species make their appearance during the day. The caterpillars have usually sixteen feet. Some have only twelve or fourteen, but the posterior or anal pair are never wanting; and in those which present but twelve the anterior pair of the membranous ones are as long as the next ensuing. The greater proportion spin a cocoon, in which they undergo their metamorphosis. These Lepidoptera correspond to the division named *Noctuæ* of the genus *Phalæna* of Linn.

All the generic groups recently established, and of which the characters are derived rather from the caterpillar than the perfect insect, are referred by Latreille to the two genera which follow. In the genus EREBUS of Lat. (Plate CCXXXVII. figs. 10 and 14), the wings are always extended and horizontal, and the terminal joint of the palpi is elongated, elevated, cylindrical, or slightly compressed, and naked. With the exception of a single species, *Ophiusa scapulosa* of Ochsenheimer, which occurs in Spain, all these insects are of exotic origin. We have figured a superb example, " the glory of the Noctuidæ," as it is well named by Mr Kirby, on the fourth plate of the first volume of our *Illustrations of Zoology*. It is the *Erebus strix* of Latreille, and is known also under the title of the

Lepidoptera Nocturna.

great owl moth of Brazil. It measures nearly a foot in breadth from tip to tip of the extended upper wings. In the genus Noctua of Fab. and Lat. (ibid. fig. 9) the terminal joint of the inferior palpi is short, and covered with scales, like that which precedes it.[1] Of those with six feet, which are the greater number, we may mention as a British species *N. sponsa*, Fab. The caterpillar lives upon the oak, is of a greyish colour, and obscurely and irregularly spotted. It is marked with small tubercles, and the eighth ring bears a projection, on which there is a yellow plate. This larva, and some other nearly allied kinds, are called *lichenées* by the French naturalists, on account of their resemblance to, and the difficulty with which they are sometimes distinguished from, various kinds of bark-supported lichens.[2] The anterior four of the membranous feet are shorter than the others, and they walk like the *surveyors*. Many other well-known species are arranged with that just mentioned. The caterpillars of certain others have only twelve feet, and the perfect insects are frequently ornamented with golden or silvery spots upon the upper wings. Such are two well-known British species, *N. gamma* and *chrysitis*. The former of these receives its name from a character resembling the Greek letter γ inscribed in gold upon its upper wings. "This creature," say Messrs Kirby and Spence, speaking of the larva, "affords a pregnant instance of the power of Providence to let loose an animal to the work of destruction and punishment. Though common with us, it is seldom the cause of more than trivial injury; but in the year 1735 it was so incredibly multiplied in France as to infest the whole country. On the great roads, wherever you cast your eyes, you might see vast numbers traversing them in all directions to pass from field to field; but their ravages were particularly felt in the kitchen gardens, where they devoured every thing, whether pulse or pot-herbs, so that nothing was left besides the stalks and veins of the leaves. The credulous multitude thought they were poisonous, report affirming that in some instances the eating of them had been followed by fatal effects. In consequence of this alarming idea, herbs were banished for several weeks from the soups of Paris. Fortunately these destroyers did not meddle with the corn, or famine would have followed in their train. Réaumur has proved that a single pair of these insects might in one season produce 80,000; so that, were the friendly Ichneumons removed, to which the mercy of Heaven has given it in charge to keep their numbers within due limits, we should no longer enjoy the comfort of vegetables with our animal food, and probably soon become the prey of scorbutic diseases."[3] The caterpillars of some other species have the habit of eating the petals of the flowers of the plants on which they dwell. The antennæ of certain kinds are pectinated, such as *N. graminis*, an insect which has sometimes proved extremely destructive to the meadows in Sweden. We may conclude by observing that caterpillars believed to belong to this genus have been seen to exercise a curious, and, as we would suppose it, an unnatural instinct,—they seize upon other larvæ, even of their own species, transfix them by the middle, and sucking out their interior juices, leave them nothing but their own skins. When we mention that Olivier (in *Encyclopédie Méthodique*) describes 459 species of the Fabrician genus Noctua, the reader will readily admit that many of the new generic groups, to which we have been unable to do more than allude, are extremely desirable, were it for nothing else than mere convenience, independent of any higher reasons resulting from the nature of things.

Section 6th, Tortrices, Linn.

These are very nearly allied to the Lepidoptera of the two preceding sections. The upper wings, of which the posterior margin is arcuated at the base and then restricted, and their short and broad contour, forming a truncated oval, bestows a peculiar physiognomy upon the species in question. They are named by the French *Phalènes à larges epaules*, *Phalènes chappes*, &c. They are all provided with a distinct trunk, and the inferior palpi are generally very like those of Noctua, but somewhat projecting. They are of smallish size, agreeably coloured, with the wings decumbent, but flattish, or almost horizontal, and covering the body,—the inner margins of the upper pair even overlapping each other a little in a state of repose. The caterpillars have sixteen feet, a smooth body, or but slightly haired, and dwell in leaves, which they roll up or convert into tunnels by means of silken cordage. They live upon the parenchyma of their own leafy dwellings, which thus serve them both for food and clothing. Others form their dwellings by uniting several leaves together, while a few are found in different kinds of fruits. Several have the posterior part of their body narrower than the others, and these were named *chenilles en forme des poisson* by Réaumur. Their cocoons are boat-shaped, and

---

[1] The genus Noctua of Fabricius, as observed by Latreille in his note to the *Règne Animal*, t. v. p. 409, is, in Ochsenheimer's *Schmetterlinge von Europa*, divided into forty-two genera, from *Acronita* to *Euclidia* inclusive. These are constituted in great part by the conversion into genera of the sections previously indicated in the "Systematic Catalogue of the Lepidoptera of Vienna." Their insertion in this article would however be still more incompatible with our own limits than with those of the *Règne Animal*, from which they are expressly excluded. The Noctuæ, according to Latreille, exclusive of *Erebus*, are resolvable into two great parallel series, one of which is related to these latter Lepidoptera, the other to the Notodontæ. The first is composed of those of which the caterpillars march after the manner of the surveyors or Geometræ. Some have sixteen feet, of which the anterior two or four of the intermediate membranous ones are the shortest; others have only twelve feet, such as *Plusia* and *Chrysoptera*, genera distinguished from the preceding by the size of the inferior palpi, which are recurved upon the head. The second series commences with species of which the palpi are proportionally larger, the antennæ pectinated, and the trunk smaller;—such are *Notodonta palpina* (*Odonptera palpina*, Lat.) and the genus *Calyptra* of Ochsenheimer. Then follow the genera *Xylena* and *Cucullia*, those Noctuæ in which the posterior margin of the anterior wings are angular or dentated, those in which the antennæ are pectinated, and those in which they are simple. The latter species are terminated by such as have an even thorax, some of which, belonging to the genus *Erastia*, seem to lead to the Pyralites. All the caterpillars of this second series have sixteen feet, with the intermediate membranous ones of equal size; their mode of progression is rectigrade. The genus *Chrysoptera* (*Plusia concha* of Fischer, in *Entomog. de la Russie*, i. *Lepidop.* iv.), with which Latreille concludes the other series, is related to *Herminia* and *Pyralis*. Thus both series seem to converge towards the latter section. The *Licheniæ*, or *Catacolæ*, of Ochs., are large species, with almost horizontal wings, which, as well as *Ophiusa*, *Brephos*, &c. appear to approximate naturally to Erebus. Latreille is of opinion that if placed in the other series they destroy its harmony.

The *Bombyx cyllopoda* of Dalman (*Analect. Entom.* 102) ought to form a new sub-genus, and of a remarkable nature, in so far as the two posterior legs of the male are shorter than the others, unarmed, and almost useless for the purposes of locomotion. This insect has the antennæ pectinated, a distinct trunk, and the palpi as long again as the head, and ought therefore to be placed near the genus *Calyptra* of Ochs. or *Herminia* of Latreille.

[2] A beautifully providential change has been rendered natural to some of these species in relation to their food. The larva of *N. algæ*, Fab. is always yellow when it feeds on *Lichen juniperinus*, which is itself of that colour; but it becomes grey while pasturing on *Lichen saxatilis*.

[3] Réaumur, *Mém.* ii. 327; *Introduc. to Entom.* i. 189.

Lepidoptera Nocturna.

are in some kinds formed of pure silk, in others of mixed materials. These insects compose the genus PYRALIS of Fab. (Plate CCXXXVII. fig. 16). Many of the species are destructive to fruit-trees and vines. *P. pomona* in the caterpillar state lives in the interior of apples, of which it eats the pippins. We may name as a British species *P. prasinaria*, which is the largest known. It measures about two inches in extent. The upper wings are pure green with two oblique streaks in the centre, the thorax is green, the under wings white. This species, with that which we have figured, form the genus *Chloephora* of Stephens.

SECTION 7TH, PHALÆNITES, Lat.

Here are comprised a numerous assemblage of nocturnal Lepidoptera, in which the body is usually slender, with the trunk either apparently wanting, or generally but slightly lengthened, and almost membranous; the inferior palpi are small and nearly cylindrical; the wings ample, extended, and almost horizontal, or flatly decumbent. The antennæ are pectinated in several males. The thorax is always even, or without a crest. The caterpillars have in general only ten legs, though some (*Ph. margaritaria*) have twelve; the anal pair are always present. These insects correspond to the *Geometræ* of Linn., and their peculiar mode of progression, already described in our observations introductory to the lepidopterous order, has obtained for them the name of *surveyors*. Their attitude in repose, also before described, is still more extraordinary.[1] They then resemble little broken twigs of the plant on which they rest; and their colours, and the inequalities of their surface, aid the deception. They thus no doubt frequently escape the observation of their natural foes. Roesel states that his gardener, mistaking one of these ligneous-looking larvæ for a dead twig, the brittleness of which he no doubt expected would admit of his instantly snapping it asunder, started back in the greatest alarm when he found by its consistence and motion that it was a living creature. The chrysalids are almost naked, their cocoons being thin and poorly supplied with silk.

According to Latreille's views, by which we are at present guided, this section, when considered in relation to the perfect insects alone, contains but a single genus, that of PHALÆNA properly so called (Plate CCXXXVII. figs. 13 and 15) of which the characters consequently agree with those just assigned to the section itself. A very different view, however, has been taken by the greater mass of entomologists, foreign and indigenous; and a roll of names of fearful length and deep construction, has been received by many as constituting a proper portion of our scientific nomenclature. Thus Mr Stephens' family *Geometridæ*, corresponding to the *Phalænites* of Latreille, contains above eighty British genera. The number is precisely eighty-three in Mr Rennie's *Conspectus*. Many naturalists believe that no such divisions as genera exist in nature, and consequently that all our generic distinctions are artificial, and constructed merely for convenience, as a helping instrument for ourselves, and an easier mode of mutual communication between ourselves and others. But all naturalists admit that there is a difference in the value of the characters chosen, and that such as are selected as generic should be pervading and influential over a pretty obvious group, not chosen arbitrarily or at hazard from the examination of the limited productions of any one confined insular region, but on mature deliberation, and after a kindly and extended study of the analogous productions of foreign lands. Characters drawn from form and structure are much less liable to accidental variation, and are likewise of more comprehensive application, than such as are derived from colour;—the former have consequently been used to distinguish the greater groups, including genera,—the latter are chiefly available in the discrimination of species, and their mode, range, and frequency of variation, of themselves afford most interesting subjects of study and reflection, in relation to the varieties of each particular kind. It is doubtful, however, whether the use of the evanescent shades of so superficial a character as colour, is advisable in the distinction of genera. The great test of a good generic character consists in its being in some way connected with or influential over the natural habits of the species which it is assumed to distinguish,—so that it may fairly be presupposed to exist in other species of similar instinctive modes of life. These traits are no doubt difficult to obtain in the insect creation, where the species are so numerous, and the gradations so often insensible from one group to another. But still we know that colour, though occasionally extremely characteristic of natural groups, is a distinction too flighty and fantastical to be generally applied with advantage, otherwise than for artificial combinations. For these and other reasons not necessary to be here adduced, we have hitherto failed to see the propriety of such characters as "first pair of wings somewhat rufous, with darker streaks," "second pair pale, with a red streak," "wings banded with green," "the first pair greenish, spotted with black, the second pair dull," &c. being adopted as *generic* distinctions,—the more especially as they would prove not very efficient even for the purposes of *specific* discrimination.

There is no doubt, however, that the great extent of the genus in question requires that it should be reduced by subdivision within manageable bounds; and if determinate and distinctive characters of sufficient value can be attached to each, a generic name may as well be used as a sectional mark. Hubner has described and figured above 400 European species, and MM. Lepelletier de Saint Fargeau and Serville have formed numerous divisions among the species described by them in the *Encyclopédie Méthodique*. Modern entomologists have adopted a method of distinguishing by the specific name alone, whether the male of a phalæna has the antennæ pectinated or setaceous. The names of such as exhibit the former structure always end in *aria*, those characterized by the latter in *ata*. A very common species is *Ph. Grossulariata*, white, with some yellow streaks, and spotted with black. The caterpillar is also richly coloured. It feeds on the leaves of the currant and gooseberry. The chrysalis is of a shining black, with yellow rings. It is known in England by the name of Magpie. *Ph. ulmata*, or the clouded Magpie, is a scarcer species. In Scotland at least it is rare. Both these belong to the sub-genus *Abraxas* of Leach. A rather large and elegant species, called the swallow-tailed moth, *Ph. sambucaria*, is of a pale sulphur colour, with two transverse streaks upon the upper, and one upon the under wings. It forms the sub-genus *Ourapteryx* of Leach, and resembles in its form the beautiful *Phalæna machaonaria* of Boisduval, which, with *Ph. guttaria*, ibid. we have represented by the figures last referred to. The females of a few present only the rudiments of wings. Such is *Ph. brumata*, which makes its appearance during the winter season, and belongs, for that reason, to the sub-genus *Hybernia* of Latreille.

SECTION 8TH, DELTOIDES, Lat.

This section consists of species very analogous to the true Phalænæ, but the caterpillars have fourteen legs, and live in rolled up leaves. The inferior palpi are elongated and recurved in the perfect insect. The wings form with the body, on the sides of which they spread horizontally, a kind of delta, with a re-entering angle in the middle of the posterior edge, producing a forked aspect. The antennæ are usually pectinated or ciliated. Our present section comprised, in the first edition of the *Règne Animal*, all the *Phal. Pyralides* of Linn. But, as Latreille has more recently observed, a complication of characters resulted from that arrangement, which is obviated by only comprising in this division the genus HERMINIA (Plate CCXXXVII. fig. 17), which belonged to *Pyralides* of Linnæus, and is composed of the genus *Hyblæa* of Fab. and several species of his genus *Crambus*. These Lepidoptera are generally of a greyish hue, without much brilliancy of colouring. Several species are remarkable for tufts of hairs upon the upper portion of their legs, the use of which in their natural economy has not yet been ascertained. Indeed we know little of the history of the species, although they sometimes attract our notice by the length of their palpi. They have been named *snouts*, *fan-feet*, &c. by the English collectors.

---

[1] See page 239.

SECTION 9TH, TINEITES, Lat.

Latreille here comprehends the *Phal. Tineæ* of Linn. and the greater part of the *Phal. Pyralides* of the Swedish naturalist. They consist of the smallest species of the lepidopterous order,—among others, of our common house-moths, so well known for their destructive propensities in the larva state, and the ravages they commit among neglected garments. These larvæ are smooth, have always at least sixteen feet, and live concealed either in fixed or moveable habitations, of their own construction. In some the wings form a kind of elongated triangle, almost flattened, and terminated by a re-entering angle;—such are the *Phalænæ Pyralides* of Linn. They have four distinct and usually exposed palpi. In others the superior wings are long and narrow, sometimes moulded on the body, and forming over it a rounded roof,—sometimes inclined almost perpendicularly, applied close to the sides, and frequently elevated posteriorly after the manner of a cock's tail in miniature. In either case the inferior wings are always broad and plaited. The latter kinds also have not unfrequently four exposed palpi.

All nocturnal Lepidoptera, the caterpillars of which lived in sheaths or cases, received from Réaumur the name of *Teignes proprement dites* or of *Teignes fausses*, according as their habitations were detached and portable by the contained creature, or fixed and immoveable.[1] This principle of arrangement, though sufficient for the purposes which the admirable author had in view, is not philosophically founded, and, if strictly applied, would require our including among the Tineites the genus *Pyralis* and others belonging to preceding sections. In the Linnæan system, our present insects composed the seventh division of the great genus Phalæna, and were briefly characterized as follows:—Wings almost cylindrically rolled, front projecting. They constitute a generic group in Geoffroy's work.[2] Following the example of Linnæus, Degeer did not separate these small creatures from the general mass of Phalænæ, but satisfied himself by forming them into different sections of his fourth and following family. Indeed his arrangement of the Phalænæ is extremely artificial.

The Tineites, although they are the pygmies of the lepidopterous order (what a vast disparity in size between a small clothes-moth and the great owl-moth of Brazil!) are much more richly attired than most of their larger brethren. Indeed, when minutely examined, not many created things will be found more worthy of our admiration; and it is not without reason that Scopoli has observed,—"Tinearum copia, parvitas, pulchritudo stupenda, ut in his potissimum natura thesauros suos effudisse videatur, tantaque in minimis hisce majestas, ut admirari potius eam liceat, quam aptis verbis indicare."[3] The wings frequently combine, with extreme beauty of colouring, the most brilliant little stripes and masses of shining silver and burnished gold, which under the microscope exhibit a most radiant richness. This lustrous aspect of many species is however but a poor recompense for the injury which we receive from many more while in the larva state. These clothe themselves at our expense in the warmest woollen garments, which they traverse in all directions, leaving behind a gnawed and worn-out path, so thin and bare as to yield to the slightest pressure. They also destroy furs, hair, feathers, and many other articles of domestic economy, and are the exterminating pests of zoological museums. To them we no doubt owe the destruction of the famous Dodo, once preserved in the Ashmolean Museum of Oxford, and never since seen by human eyes. By means of their maxillæ these little larvæ shear down the surface of various substances, and uniting the particles by means of their glutinous silk, they thus form protecting habitations, which partake of the nature of the woollen or other stuffs on which the foresight of their parents has placed them. When they themselves increase in bulk, so as to find their abodes as inconvenient as a strait waistcoat, they split them down the middle, and interpose a piece, proportioned no doubt to their expected as well as actual increase. They add to the length also by fresh materials to the anterior end. These observations are easily made by removing the young larva in its first restricted case, from a piece of white to a piece of scarlet or other coloured flannel. When about to undergo their transformations they close up the apertures with silk. Another larva of this section (*Teigne des blés*), which Olivier makes an *Alucita* and Latreille an *Œcophora*, is still more destructive on account of its ravages among corn, and its prodigious powers of multiplication. Our grain is also liable to great damage from the larvæ of other Tineæ, such as the *fausse chenille des blés*, described by Réaumur, which, by means of its silken web, connects together several grains in the form of a tunnel, from which it issues forth to feed on the neighbouring heaps. It is a somewhat analogous species which in bee-hives pierces the waxen cells on which it feeds; and by thus causing the honey to flow out, occasions great loss to the apiarian. Our readers must have frequently observed the leaves of many plants and trees pervaded by numerous tortuous windings, of a paler colour than the rest. These are the sub-cutaneous galleries of certain very small larvæ of garden-moths, many of them extremely beautiful, and so minute as to dwell at ease between the upper and under surface of the leaf. Others dwell and feed upon the surface, but screened from immediate observation by a covered way of silk, which they spin along their devious courses. Referring the curious reader to the works of Réaumur, Roesel, and Degeer, for a more ample history of these truly singular and interesting tribes, we shall here briefly notice a few of the principal genera.

In the following groups the four palpi are always dis-

---

[1] The *Teignes aquatiques* of Réaumur are the larvæ of *Phryganeæ*; and those to which he applies the ancient name of *Ligniperdæ* are the larvæ of the genus now called *Psyche*, belonging to the section *Pseudo-Bombycites*.

[2] *Histoire des Insectes des Environs de Paris.*

[3] *Entomologia Carniolica*, p. 243.

Lepidoptera Nocturna.

tinct,[1] exposed, or simply concealed (the upper ones), in part by the scales of the epistoma, and are advanced, of medium size, and analogous to those of the *P. pyralides* of Linn. Their wings are decumbent, generally flattened, or but slightly raised, and form a kind of delta or elongated triangle. In the ensuing genera the trunk is apparent, and serves for the performance of the usual functions. The larvæ live on various plants. In Botys, Lat. (CCXXXVII. fig. 11), the larvæ roll up leaves, and do not differ externally from the others except in the respiratory organs. In Hydrocampe, Lat. (ibid. fig. 12), the species are analogous to the preceding, but the caterpillars are aquatic, and are usually furnished with filiform appendages, the interior of which contain tracheæ. They fabricate tunnels or covered ways with the leaves of various aquatic plants. Such are *H. potamogata*, *paludata*, *lemnata*, &c. In the genus Aglossa of Lat. (ibid. fig. 19) the trunk is wanting, or nearly so. The four palpi are exposed, and the wings form a flattened triangle,—the upper having no emargination at their extremity. *A. pinguinalis*, Réaum. iii. xx. 5–11, occurs on walls in houses. The caterpillar is smooth or short-haired, of a brownish black, and shining. It feeds on various fatty substances, and also attacks leather,—on which account it is called *fausse-teigne des cuirs* by Réaumur. It is destructive to the binding of books, and is therefore an inconvenient companion in a library. Its case consists of a long tunnel, applied close to the substance on which it lives, and covered by particles of excrementitious matter. According to Linnæus, it occurs, though rarely, in the human stomach, where it occasions effects much more dangerous and alarming than those caused by ordinary intestinal worms. " Un médecin éclairé, " says Latreille, " et dont je ne puis révoquer en doute la véracité, m'a envoyé des chenilles de cette espèce, qu'une jeune famille avait vomies." Another species, *P. farinalis*, feeds on flour. In the genus Galleria of Fab. the scales of the clypeus or epistoma form a projection which covers the palpi. The upper wings, proportionally narrower than those of Aglossa, and emarginate on the posterior border, are, in common with the inferior, very decumbent, and raised posteriorly like a cock's tail, as in many species of the ensuing genera. *G. cereana*, Fab. is the species the larva of which is designated *fausse-teigne de la cire* by Réaumur. It is extremely destructive in bee-hives, in which it pierces the honey cells, and constructs as it advances a silken tunnel covered with excrementitious particles composed of the wax which it has devoured. The cocoons of the chrysalids are sometimes found assembled in heaps.

In other groups of Tineites the superior palpi are not always very distinct. The upper wings are long, narrow, sometimes moulded or rolled upon the body, sometimes applied perpendicularly to the sides. In this state the insect has always an elongated and narrow form, approaching that of a little cylinder or cone, when the wings are closed.

In the next-named four genera the inferior palpi, always large, are borne, as it were, in advance, the last joint at most being raised. The palpi are apparent. Crambus, Fab. (Plate CCXXXVII. fig. 20), has a distinct trunk. The inferior palpi project straight forwards like a beak. These Lepidoptera occur in dry pastures and on various plants. Alucita, Lat. (ibid. fig. 22), has also a distinct trunk, but the inferior palpi are raised. The antennæ are simple. In Euplocampus, Lat. (ibid. fig. 18), the trunk is short and inconspicuous, and the last article of the inferior palpi is likewise raised, the scales of the preceding one forming a faisceau. The antennæ of the males are furnished with a double row of little barbs. The genus Phycis of Fab. is closely allied to Euplocampus, but the antennæ at most are merely ciliated.

In the following genera the inferior palpi are entirely raised, and even recurved over the head in several. Sometimes the inferior palpi are very apparent, and of medium size. The antennæ and the eyes are distinct. In the two following genera the inferior palpi scarcely surpass the front. In Tinea (ibid. fig. 21) the trunk is very short, and formed of little membranous disjointed threads. The head is erected. The species of this genus, which has been greatly restricted since the time of Fabricius, are particularly destructive among our clothes and other household concerns. We shall here notice a few of the principal kinds. *Tinea tapezana*, Fab. and Lat., has the upper wings black on the basal portion, their posterior part being white. This is the species represented by our figure.[2] Its caterpillar feeds on woollens, on which it forms an arched gallery, lengthening as it advances. *T. sarcitella* is of a silvery-grey colour, with a white spot on each side of the thorax. Though very abundant and extremely destructive in most parts of Europe, its synonymy and consequent history are somewhat confused. The figures given by Réaumur,[3] and cited by many authors, appear (at least if we judge from the eleventh) to belong to another genus. The inferior palpi are large, recurved and pointed, a character which rather allies it to the genus *Volucra* of Lat.[4] and to the *T. vestianella* of Scopoli and Linn. It is even suspected that these two insects are the same. According to the last-named authority, the *T. sarcitella* is of a silvery grey, as above described. In *T. vestianella* the upper part of the head, of the thorax, and even the base of the superior wings, are white. The inferior palpi, recurved in the manner of horns, are of the same colour, ringed with black. The wings lie horizontally on the body, are whitish, and shining, and the upper surface of the superior pair presents some blackish spots of different sizes. The inferior are of a uniform colour, bordered posteriorly, as is also the internal margin of the upper pair, with long fringes. This species is extremely common, and it has been presumed that Linnæus having given an inadequate description from a defective specimen, its identity became difficult to recognise, and that thus Scopoli bestowed a new name, that of *vestianella*, upon an old species.[5] However this may be, the *T. sarcitella* is extremely pernicious among all woollen substances. It forms and inhabits a silky case, usually spindle-shaped, which it covers with detached hairs or particles of wool. *T. pellionella*, Fab. has the upper wings of a silvery grey, with one or two black points on each. Its caterpillar forms a felted case or tunnel, and lives on furs, which it destroys with ease and satisfaction to itself, by gnawing off the hairs at the base. The wings of *T. granella* are elevated behind, and marbled with grey, brown, and black. Its larva is very injurious to grain. *T. flavifrontella*, Fab. has a *toupee* of a more lively colour than the other parts, approaching to reddish. Its larva forms a silken case, and is extremely hurtful in museums, among birds, insects, &c.

---

[1] The genera *Iponomeuta* (with one or two exceptions), *Œcophora*, and *Adela*, are, according to Latreille, the only Tineites of which the superior or maxillary palpi are not distinctly perceptible; but as they may be concealed by the inferior or labial palpi, it is difficult, in relation to this point, to establish a fixed and rigorous line of demarcation. For this reason the French entomologist has not arranged the Tineites according to the number of the palpi. M. Savigny, in his *Memoires sur les Animaux sans Vertèbres*, has given figures, in which these parts are represented in their various proportions. (*Règne Animal*, v. p. 417.)

[2] It is identical with *T. tapetzella* of Linn. and the lamented Mr Haworth.

[3] *Mémoires*, iii. vi.

[5] See *Dict. Classique d'Hist. Nat.* xvi. p. 87.

We may conclude by observing, that the most efficient means of preventing or removing moths are care and cleanliness. Let articles of such a nature as may be liable to their injurious inroads be frequently examined, handled, and exposed to light and air. These tiny creatures are lovers of darkness, and of undisturbed repose. The instinct of the mother (and that providential perception is never more unerring than when manifested in relation to the welfare of a future offspring) teaches her to distinguish whatever is neglected or cast aside,—and in like manner she becomes sensible that whatever is used or often handled would form an unsafe nidus for her tender young. In depositing her eggs she therefore selects the one and rejects the other; and hence a careful housewife, who feels a lively interest in her own concerns, and frequently examines and refolds or arranges her household gear, may live for half a century and never see a moth. At the same time, if articles are rolled up in a perfectly close and well-ordered tissue, they are safe from these destructive creatures, which are certainly never *bred* from the things they consume, however old or ill-conditioned. But if a single unsuspected crevice should chance to admit one solitary female moth, "the spinster's occupation's gone," and a colony of worms is suddenly produced from innumerable eggs, which would strike horror into the heart of a Malthusian. Where things must be left unexposed to changes of light and air, and yet cannot be hermetically closed, the use of camphor, spirit of turpentine absorbed upon pieces of sponge or cotton, and other preventives, are tried with more or less success. Exposure to a brisk fire is the most effectual means of expelling the larvæ from stuffed birds, quadrupeds, &c.

In the genus ILITHYIA, Lat. (Plate CCXXXVII. fig. 23), the inferior palpi resemble those of the preceding genus, but the trunk is distinct, and of the ordinary size, and the last article of the inferior palpi is obviously shorter than the preceding. In IPONOMEUTA, Lat. (ibid. fig. 24), the trunk is also distinct, and of tolerable size, but the terminal article of the inferior palpi is at least as long as the preceding one. These insects, according to Latreille, are related to Lithosia. *Y. evonymella* (Tinea of Fab.) has the upper wings of a shining white spotted with black, the inferior pair lead colour. *Y. padella*, Lat. has the upper wings of a greyish-lead colour, and very numerously spotted with black, the under pair lead coloured, with thick fringes. The caterpillars of both these kinds live in large congregations, beneath a dusky web, which they stretch out upon our fruit-trees, of which they devour the leaves. When they have eaten all within their reach at one place, they make a start to another, enclose themselves under a new and more extended canopy, and recommence their ravages, which are found to be extremely injurious to the health of the tree, and its productive powers. The branches seem as if covered with patches of dusty and discoloured crape. In the genus ŒCOPHORA, Lat. the inferior palpi are recurved above the head, in the manner of horns, proceeding to a point, and reaching as far backwards as the back of the thorax.

Lastly, in a few species, such as those of the genus ADELA, Lat. (Plate CCXXXVII. fig. 25), the inferior palpi are very small and clothed, the antennæ are almost always extremely long, and the eyes approximate. These beautiful little creatures occur in woods, and are said to appear with the leafing of the oak. They are frequently brilliantly ornamented with metallic scales. The species which we have figured is *A. Degeerella*, remarkable for its antennæ being many times the length of its body. These delicately articulated organs are whitish, the posterior portion black. The upper wings are of a gilded yellow on a dark ground, forming longitudinal streaks, with a broad transverse golden-yellow band bordered with violet.[1]

SECTION 10TH, PTEROPHORITES, Lat.

This, our concluding section of the nocturnal Lepidoptera, exhibits many relations to the preceding, in respect to the narrow and elongated form of the body and upper wings; but it differs from it, as well as from all the other sections, in this, that a pair, if not all, of the wings, are as it were split or cloven throughout their whole length, so as to present a branched or digitated appearance, bearded on the edges. The parts look like feathers, so that the wings of these fantastically formed creatures somewhat resemble those of birds. They formed the division of *Phalænæ alucitæ* of Linnæus, and were named Phalènes-tipules by Degeer. Geoffroy, Fabricius, and Latreille include them under the genus PTEROPHORUS. Their larvæ have sixteen feet, live on leaves and flowers, and construct no cases. The chrysalids of the greater number are naked, coloured, and suspended by a thread. In others they are enclosed in a translucent cocoon. The genus has been lately subdivided. In some the inferior palpi are recurved from their origin, entirely garnished with small scales, and do not exceed the length of the head; these constitute the genus PTEROPHORUS properly so called, of Latreille (Plate CCXXXVII. fig. 26). Their chrysalids are exposed, beset with hairs or small tubercles, and are sometimes suspended by a thread, sometimes fixed by means of hooks at the posterior extremity to a little bed of silk, imposed upon a leaf or other vegetable body. *P. pentadactylus*, Fab. is an example of this division. The wings are of an almost snowy whiteness, the upper pair being divided into two, the lower into three parts. In others the inferior palpi are projected, longer than the head, with the second article thickly covered with scales, and the terminal one almost naked, and turned up. The chrysalis is enclosed in a cocoon of silk. To these Latreille has applied the generic name of ORNEODES (ibid. fig. 27). The *O. hexadactylus* measures about six lines in length. It is of an ash-coloured grey, with a tinge of brown. The wings, especially the upper ones, are traversed by obscure or blackish bands, with some spots of a paler grey; and each wing is divided to its base into three principal parts, of which the first is subdivided into two radii, and the second into three: the third is simple. The caterpillar of this species has sixteen feet, and lives on the honeysuckle, *Lonicera xylosteum*. The perfect insect is often found on walls and windows, and in the interior of houses. It is widely spread over Europe.

We here take leave of the lepidopterous order, and shall only further remark, that we seek in vain to express by words the splendid colours, the elegant and varied forms, and the exquisite pencilling, by which they are adorned. Even the most richly illumined pages of natural history convey but a meagre image of their gorgeous attire. That must be sought for—where alone it can be found,—in those far more brilliant and inimitable pages of the *book of nature*, in which the most successful effort of art is transcended by a feeble insect's wing. The imagination of poet and of painter cannot boast,

---

[1] In the arrangement of these insects, given by Latreille in the second edition of the *Règne Animal*, and by which we have been guided above, he has apparently, with the view of approximating to the nomenclature of Réaumur, combined the *Pyralides* and *Tineites* in one section. He has however elsewhere indicated the propriety of their being disjoined, and in this event the following genera will compose the Tineites: I. Inferior or labial palpi advanced; the terminal articulation at most elevated; superior palpi apparent: Genera GALLERIA, CRAMBUS, ALUCITA, EUPLOCAMPUS, and PHYCIS. II. Inferior palpi altogether elevated, or even recurved, in several, over the head. A. Inferior palpi of medium size, and very obvious; eyes distant: Genera TINEA, ILITHYIA, IPONOMEUTA, ŒCOPHORA. B. Inferior palpi very small and hairy; eyes approximate: Gen. ADELA.

> Amid their gay creation, hues like these.

ORDER VII.—STREPSIPTERA, KIRBY.[1]

The singular insects which constitute our present order are parasitical species, which dwell, while in the larva state, between the plates of the abdomen in different kinds of wasps and bees. Their characters were first given by Mr Kirby (*Linn. Trans.* vol. xi. p. 109), who bestowed upon them the name above adopted, and which was subsequently altered, without sufficient reason, by Latreille. The definition given by the former author, in his later work, is as follows: Metamorphosis sub-incomplete? Pseudelytra twisted, attached to the anterior leg. Wings not covered by the elytra, longitudinally folded, forming nearly the quadrant of a circle: neuration simple. Anus styliferous.[2] On each side of the anterior extremity of the thorax, near the neck and the exterior base of the first pair of legs, are inserted two small crustaceous bodies, like rudimentary elytra, stretching backwards, curved, dilated, and terminating near the origin of the true wings. These are the *pseudelytra* just named, called *prebalanciers* by Latreille. The great French entomologist is of opinion, that, as elytra properly so called always cover the totality of the base of the membranaceous wings, and derive their origin from the second segment of the thorax, the parts in question are not genuine wing-cases, but rather analogous to the tippets (*pterygoda*), observable at the base of the upper wings in the lepidopterous order. The actual wings of Strepsiptera are large, membranaceous, divided by longitudinal nervures, proceeding like rays from the shoulder or point of union with the body. They fold lengthways like a fan.[3] The mouth is composed of four pieces, of which the shorter two appear to be biarticulate palpi, the others, inserted near their base, have the form of little linear laminæ, pointed, and crossing at the extremity, like the mandibles of various insects, but resembling rather the lancets of the sucker of the dipterous tribes, than true mandibles.[4] According to Savigny's views, the mouth consists of a labrum, two mandibles, a pair of maxillæ, each bearing a very small uniarticulate palpus, and a labium without palpi. The head presents two large eyes, hemispherical, granose, and slightly pediculated; two antennæ, approximate at the base, placed upon an elevation in common, almost filiform, short, and composed of three articulations, of which the first two are very short, and the third, greatly elongated, is divided from its origin into two long compressed lanceolate branches, applied against each other. The stemmatic eyes are wanting. The thorax, in its peculiar form and divisions, resembles that of several Cicadariæ, Psyllæ, and Chrysides. The abdomen is nearly cylindrical, composed of eight or nine segments, and is terminated by pieces which seem to bear an analogy with those which we find at the posterior extremity of the Hemiptera above named. The six legs are almost membranous, compressed, nearly equal, and terminate in filiform tarsi, composed of four membranous articulations, which appear vesicular at their extremity, and of which the terminal one, somewhat larger than the others, is unfurnished with hooks. The four anterior legs are approximate, the posterior pair being thrown pretty far back by themselves. The space comprised between the latter pair is ample, and divided into two by a longitudinal groove or furrow. The posterior extremity of the metathorax is prolonged over the abdomen in the manner of a large scutellum, and its sides, which serve as points of insertion to the posterior legs, are much dilated backwards, and form a kind of inflated buckler, which defends the exterior and lateral base of the abdomen.

These singular insects were first observed by Rossi, who concluded, because they were parasitical, that they must belong to the hymenopterous order, to which they certainly bear a greater affinity than to any of the dipterous tribes, among which they were arranged by M. Lamarck. Latreille inclines to consider them as related (although at the same time differing in various ways) to certain hymenopterous species, such as those of the genus EULOPHUS. In the larva state they live between the abdominal plates of hymenopterous insects belonging to the genera *Andrena* and *Polistes*. It has been supposed that the elytra-like portions, already described, serve to disengage the perfect insects with greater facility from the living chambers in which they are incased. They are said to frisk about with a simultaneous motion of these organs and the true wings. Latreille calls them the *Œstri* of insects. We know that a species of Conops likewise undergoes its transformations in the interior of a Bombus, or wild bee.

This order contains only two genera,—XENOS of Rossi, and STYLOPS of Kirby. Their exact nature is still of difficult determination, as will be perceived from the following quotation:—"The true place in nature," says Mr Macleay, "of the singular genera *Xenos* and *Stylops*, is indeed very difficult to determine; and what remarks, therefore, I am now about to offer on them ought to be received by the reader with great caution, as well because it has hitherto been out of my power to become acquainted with them, except through the medium of the works of Kirby, Latreille, Savigny, and Lamarck, as because the total variance in the statements of these authors respecting them demonstrates that their true nature is as yet by no means ascertained.

"Professor Peck and Savigny, however, have both most satisfactorily shown that the *Strepsiptera* are provided with true mandibles and palpigerous maxillæ; and therefore have completely set aside the opinion of MM. Lamarck and Latreille as to their affinity with the *Diptera*. Proceeding, then, on the fact that they belong to the *Mandibulata*, which, by the by, appears at last to be admitted by Latreille, we necessarily make inquiry as to the particular part of this class in which they ought to be placed. Now, the only chasms of importance which we have noticed in the column, are one between the *Trichoptera* of Kirby and the *Tenthredines*, and the other between the *Hymenoptera* and the *Coleoptera*. The deficiency of ocelli, the structure of the whole insect, but particularly that of the wings, prove that the *Strepsiptera* cannot occupy any vacancy near the *Trichoptera*. It therefore only remains for us to place them between the *Hymenoptera* and *Coleoptera*. But this appears to be nearly the situation originally given to the *Strepsiptera* by Mr Kirby; for, in his very remarkable paper on those insects, in the eleventh volume of the *Linnæan Transactions*, he says, 'With respect to the place of *Strepsiptera* in the system, it seems to me that this order should follow *Coleoptera*; for its metamorphosis being different from that of *Orthoptera* and *Hemiptera*, and nearer to that of the *Coleoptera*, this seems its most natural station, considered as an elytrophorous order, especially since, if it be inserted between *Orthoptera* and *Hemiptera*, with both of which it has some affinity, it would interrupt the series of semicomplete metamorphosis, by which, besides other characters, these two orders are so closely united.' He had previously noticed a circumstance which at once distinguishes them from all *Coleoptera* and *Orthoptera*, and gives them an affinity with the *Hymenoptera*, namely, a narrow collar instead of an ample thoracic shield. And it is worthy of remark that Rossi, in the work which informed naturalists of their existence, placed them among the *Hymenoptera*, induced to this, as Mr Kirby supposes, by the economy of their larvæ. Such, then, is in all probability their true place in nature, though certainly my opinion on the subject, for the reasons already stated, ought to be received, as it is advanced, with great caution. The *Xenos*, beyond a doubt, is, with the *Stylops*, the most puzzling insect to place naturally that we know; it is truly '*animal animum excrucians*;' and no better proof of this can be given than that when Lamarck and Latreille make the *Strepsiptera* a division of *Diptera*, they seem absolutely to have pitched on the most artificial situation for them which they could have chosen. Latreille has remarked that the body of the *Strepsiptera* bears a striking relation to that of some *Homoptera*; and to judge from the descriptions given by Mr Kirby of these insects, their wings are folded like those of *Orthoptera*, while the form of their head resembles that of some *Neuroptera*. To the *Diptera* they have no visible affinity, and scarcely any analogy, except such as we might expect from their proximity to the *Hymenoptera*. How far I am right in adopting Mr Kirby's opinion as to their real affinities, remains yet to be seen; but it is no weak argument in support of its accuracy, that they possess the very precise kind of metamorphosis which insects in the hiatus between the *Coleoptera* and *Hymenoptera* ought to have from analogy.

[1] RHIPIPTERA, Lat.

[2] *Introduc. to Entomology*, iv. 370.

[3] Hence the name of *Rhipiptera*, bestowed upon them by Latreille, from ϱιπις, *a fan*, and πτεϱα, *wings*.

[4] *Règne Animal*, v. 425.

"The *Strepsiptera* ought probably to be considered as an osculant order; and they undoubtedly form a group which is apparently of much greater importance, and is marked with much stronger characters, than the *Dictuoptera*. These can scarcely be said to afford a type of any very peculiar construction, and may therefore, perhaps, with more propriety, be viewed as an annectent tribe falling into the extensive order of *Orthoptera*."[1]

In the genus STYLOPS, the last portion of the antennæ is composed of three small articulations. The abdomen is fleshy and retractile. *S. Melittæ*, Kirby, measures about a line and a half in length, and is quite black, with brown legs. The wings are longer than the body. The larva is soft, almost cylindrical, and whitish. Its head is advanced, horny, heart-shaped, a little flattened, of a reddish colour, black posteriorly, and somewhat concave beneath. It lives in the bodies of *Andrenæ*, and when about to be transformed to a chrysalis or pupa (Plate CCXXXI. fig. 29), it fixes itself more outwardly, between the abdominal plates. It occurs in Britain and the continent of Europe. Additional species have been lately discovered by Mr Dale and others, and will be found described in the works of Messrs Curtis and Stephens.

In the genus XENOS established by Rossi,[2] and so excellently illustrated by Mr Kirby,[3] the terminal branches of the antennæ are not articulated. The abdomen is corneous with the exception of the termination, which is fleshy and retractile. We are acquainted as yet with the detailed history of only two species. The first is the *Xenos vesparum*, now called *X. Rossii*, in compliment to its discoverer. It inhabits, and is frequently found in, a European hymenopterous insect or wasp called *Vespa* (*Polistes*) *gallica*. The individuals of the latter kind infested by the Xenos are readily known by the unnatural swelling of the fourth segment of the abdomen, from which the insect in the perfect state is usually found to emerge. Sometimes one, not seldom two, and occasionally three, are seen to escape from the same wasp. They generally come forth in the winged state in August and September; and if during that period the pupa be extracted with a needle from the abdomen of the wasp, the covering broken open, and the white tunic carefully stripped away, living specimens may be obtained. The mode in which these parasites are originally placed on their living prey is not yet known. It is possible that the egg may be laid in the larva of the wasp before its cell is closed. Rossi at least seems to be of this opinion, although Mr Kirby, reasoning from analogy, thinks it unlikely that it should be deposited on the wasp in its first state, while the larva feeds on it in its last. It has been a subject of wonder to naturalists that these Vespæ, after supporting one or more parasites, should survive; yet we know that they are often met with in a most active and vigorous condition, with only the exuviæ of the Xenos remaining in them. It has been stated as an explanation of this, that the time during which the insect remains in the larva state is very short; and as it does not attack the thorax of the wasp, the muscular energy and general vital powers of the latter thus escape destruction. The other species to which we alluded is the *X. Peckii* (Plate CCXXXI. figs. 30 and 31), so named after an American naturalist, Professor Peck, by whom it was made known to Mr Kirby. This species measures one and a half lines in length. It is of a blackish-brown colour, the legs livid, the tarsi brown. The branches of the antennæ are subdiaphanous, and spotted with white. The larva inhabits a North American wasp called *Polistes fuscata*, of which it so distorts the abdomen that, according to Professor Peck, there is no difficulty in distinguishing the infested individuals even on the wing. "Taking them," he observes, "with the gauze forceps, bringing them into a close room, and permitting them to fly to the windows, I caught them again with a wine glass and a card, fed them with sugar, and thus preserved them till their parasites were disclosed. I had not the pleasure to see them emerge, but found them soon after." "In the feeding state the head of the larva is near the abdomen of the wasp, as I found by dissection. When the feeding state is passed, it is easy to conceive that it turns, and with its flattened head separates the membrane which connects the abdominal scuta, and protrudes itself a little way, accurately closing the aperture, which is but just large enough to admit it. All this time the wasp is active, and associates with its companions. When just protruded, the head of the larva is of a pale-brownish colour; by degrees it assumes a rounder form, and becomes almost black. The chrysalis state ensues; but I suspect that only the part exposed to the air, and that immediately under the pressure of the abdominal rings, becomes hard."[4]

We shall now pass from this limited order to one of much greater extent and more ancient constitution.

ORDER VIII.—DIPTERA.[5]

The numerous order of dipterous or two-winged insects, of which the common house-fly affords a familiar example, is characterized by possessing a pair of veined and membranous wings, with two moveable bodies called balancers (*halteres*) placed a little behind them. The mouth consists of from two to six setaceous pieces of a scaly texture, and its parts are either enclosed in the upper groove of a probosciform sheath, terminated by two lips, or covered by one or two inarticulate laminæ, which form the sheath.[1]

[4] *Linn. Trans.* vol. xi. p. 90.

[5] ANTLIATA, Fabricius.

Dipterous species, like all other hexapod insects, are composed of three principal portions. The head is more or less globular or hemispherical, often concave posteriorly, so as to fit better on the front of the thorax, and is susceptible of turning on itself, as on a pivot, from right to left, and *vice versa*. The greater part of its surface, especially in the males, is generally occupied by the eyes, which are often very beautiful, being composed of a vast number of facettes, lighted up as it were with a metallic splendour. When ocelli or stemmatic eyes exist in this order, they are always three in number, and placed upon the vertex. When the mouth (which is not adapted for chewing or bruising solid substances, but only for extracting and transmitting fluids) consists of six pieces, it then exhibits all the parts analogous to those of masticating insects. Of these parts a single superior portion represents the labrum, and a single inferior portion the ligula properly so called, of the coleopterous and orthopterous orders. The four other parts are disposed in pairs; the upper pair corresponding to the mandibles, the lower to the terminal portion of the maxillæ of the masticating orders. The basal portion of the maxillæ also exists, but it is always very short, and confounded with the fleshy mass, which serves as the base of the trunk, and precedes its first geniculation. Thus in the Muscides, for example, the sucker consists of only two setæ, and is yet accompanied by a pair of palpi, which, according to analogy, can only be those of the maxillæ. Seeing that the piece representing the labrum is inserted, with the other portions of the sucker, near the geniculation of the trunk, and at some distance from the anterior margin of the head,—and that, in other insects, the labrum is always fixed to that margin,—it becomes necessary that a portion of the base of the clypeus, or epistoma as it is now called, should be incorporated with the support of the sucker. We have just stated that the inferior portions of the maxillæ are likewise united with the supporting part, which, when not in action, is withdrawn into the oral cavity. It is not thus with the Lepidoptera and Hemiptera,—the corresponding portion of the maxillæ in these orders being fixed and immoveable, and the labrum always preserving its relative position. In some Diptera the sucker is composed of only four pieces, and then the *mandibular* setæ are wanting or imperceptible. Indeed in a great number we perceive only two pieces, and in that case it is the single pieces only (*impaires*), that is, the labrum and ligula, which are cognisable. The reduction in the number of these parts is, according to Latreille, a proof of the inferiority of the dipterous order, when compared with the generality of insects. The sucker in our present order performs the office of a lancet, by piercing the envelope of vegetable fluids, or the vessels which contain the juices of animals. These liquids, by pressure of the parts, are then forced to ascend the internal canal to the pharynx, situate at the inner base of the sucker. The lancets are often grooved or furrowed, by which they become more compactly enclosed, and act in common. The sheath or external part merely serves to maintain the lancet *in situ*, and seems to represent the lower lip of the triturating orders. It is frequently bent upon itself, at an angle more or less acute, when the insect is using the sucker. This becomes obvious when we examine a gnat or mosquito in the act of pumping our blood.

The antennæ of the Diptera are usually inserted on the front, and are approximate at their base. In the family called Nemocera by Latreille (*Culex* and *Tipula*, Linn.), these organs resemble those of the nocturnal Lepidoptera in form and position, but in his other families they seldom consist of more than two or three articulations, the last of which is fusiform, or shaped like a lenticular or prismatic pallet, provided either with a little styliform appendage or a thickish hair or seta, itself sometimes simple, sometimes pilose.

The thorax appears as if composed of only a single segment, the first, or prothorax, being very short, or sometimes evanescent, and the metathorax being also very short, and occupying only the posterior extremity, situate beneath the scutellum. The mesothorax, or intermediate portion, thus becomes the principal apparent segment. It bears on each side a pair of stigmata, of which, however, the anterior is frequently alone distinguishable.

The neuration of the veins of the wings is simple. These parts are usually horizontal. Meigen's figures of the wings (of which we have availed ourselves in the plates connected with this article) are extremely exact. He confines himself, however, chiefly to the antennæ in the formation of his generic characters, without having recourse to Jurine's method of employing the neuration of the organs of flight,—a method, indeed, the application of which in the dipterous tribes is attended with greater difficulties than among the hymenopterous order. It has, however, been used in relation to the Diptera by Fallen, and other systematic authors.

Above the true wings, and a little behind them, are two small moveable bodies, almost membranous or slightly corneous, usually pale in colour, nearly linear in the greater part of their extent, but with a knob or button-like mass at the extremity, capable of dilatation. These are the balancers or *halteres*, of the nature and supposed uses of which we have already spoken at sufficient length in our general introductory observations.[2]

Above the balancers we find two membranous or papyraceous pieces, usually white or yellowish, ciliated, united together by one of their sides, and having the form of two valves of a shell applied upon each other. These are the winglets, or *ailerons* of the French writers.[3] Their size seems to be in an inverse proportion to the length of the balancers, which to a certain extent they cover and protect. One of them is attached to each of the corresponding wings, and participates in its movements,—but during flight the valves are held in separation, or nearly on the same plane.

The abdomen of dipterous insects is frequently attached to the thorax by a portion only of its transverse diameter. It is composed of from five to nine apparent segments, and in the females usually terminates in a point; in those, however, in which the segments are fewer, the terminal ones form a kind of ovipositor, presenting a succession of small tubes which slip into each other somewhat after the fashion of the different portions of a telescope. It results from this conformation that several of the hinder stigmata are by no means distinctly perceptible.

The legs are usually long and slender, and are terminated by five-articulate tarsi, with two hooks at the extremity, besides, in many instances, two or three small cushion-like expansions, either membranous or vesicular. It is by means of these last-mentioned parts, according to certain authors, that flies are enabled to creep up the smoothest perpendicular surfaces, or to walk on ceilings with their backs downwards.[1]

---

[1] See Plate CCXX. fig. 7, *a*, *b*, *c*, *d*,—and the detailed description given at page 69, note 4.

[2] See page 75, note 2.

[3] We name them *wing-scales* in the ensuing portion of this treatise, from the German word *schuppschen*, used by Meigen.

Dr Derham had long ago observed that "diverse flies and other insects, besides their sharp-hook'd nails, have also skinny palms to their feet, to enable them to stick on glass and other smooth bodies, by means of the pressure of the atmosphere."[2] This opinion, very generally adopted by entomologists, derived additional weight from Sir Everard Home's papers on the subject, illustrated by drawings from the always admirable pen of Mr Bauer.[3] The structure of the parts, however, has been variously described by different authors, and by some in such a manner as (supposing their descriptions accurate) to render the organs unfit for the uses supposed, or at least for the particular mode of action assigned by Derham and Home, and coincided in by Messrs Kirby and Spence.[4] Thus Dr Hooke described the house-fly as having the soles of its feet beset underneath with small bristles or tenters, like the wire teeth of a card for working wool, and which he conceived to give them a strong hold upon any object having irregular or yielding surfaces. In regard to glass, which is neither yielding nor irregular, he imagined that it bore upon it a kind of smoky substance, penetrable by the points of the bristles.[5] The want of accordance in these accounts lately induced Mr Blackwall to inspect the parts minutely under a good compound microscope, when he immediately became convinced that the function assigned by the writers we have first named was incompatible with the actual organization. "Minute hairs," he observes, "very closely set, and directed downwards, so completely cover the inferior surface of the expanded membranes, improperly denominated suckers, with which the terminal joint of the tarsi of flies is provided, that it cannot be brought into contact with the objects on which those insects move, by any muscular force they are capable of exerting. The production of a vacuum between each membrane and the plane of position is therefore clearly impracticable, unless the numerous hairs on the under side of these organs individually perform the office of suckers; and there does not appear to be any thing in their mechanism which in the slightest degree countenances such a hypothesis."[6] Mr Blackwall then procured living specimens of the house-fly, *Musca domestica*, and of the large flesh-fly, *Musca vomitoria*, and enclosed them in clear jars and phials of transparent glass, the interior surface of which they traversed in every direction with the greatest facility, even walking upon it with their backs downward, while they remained in full vigour; but when enfeebled either by exposure to cold or by the fatigue of over exertion, the identical individuals ascended the sides of the same jars and phials with difficulty (falling from them frequently), and were altogether incapable of adhering in an inverted position. No sooner, however, were they recruited by repose or an increase of temperature, than they again repeated those extraordinary feats, to which custom makes us callous, with all their original dexterity. He likewise found, that flies which are unable to maintain an inverted position on highly polished bodies, will frequently adhere firmly, with their backs downward, to glass defective in polish or slightly soiled. This and other facts plainly indicated that flies are not supported on the vertical sides of smooth bodies either by the pressure of the atmosphere or by the aid of a glutinous secretion (as conjectured by some authors), but by means strictly mechanical, as suggested by Dr Hooke. It has been found, in fact, that the house-fly, while it retains its vital powers unimpaired, can not only traverse the upright sides, but even the interior of the dome of an exhausted receiver; and that the cause of its relaxing its hold, and ultimately falling from the station it occupies, is a diminution of muscular force attributable to impeded respiration.[7]

In regard to the anatomical structure of the dipterous order, the following is the substance of the observations on the subject given by M. Marcel de Serres, in his admirable memoir *Sur le Vaisseau dorsal des Insectes.* The dorsal vessel (now regarded as the heart) is itself narrow, and its pulsations frequent. The respiratory system consists of vesicular tracheæ, communicating with each other by tubular tracheæ, and unfurnished with those cartilaginous hoops which we find in the Orthoptera. The nervous system is generally composed of a small cerebriform ganglion with approximated lobes, from which proceed large optic nerves; two medullary cords of the ordinary kind (already described in our preceding general introduction) form from space to space about nine ganglia, of which three belong to the thorax and six to the abdomen. The intestinal tube presents, 1*st*, an œsophagus extending to the base of the abdomen; 2*d*, a rather elongated stomach, somewhat narrow, and furnished at its origin with a considerable number of hepatic vessels; 3*d*, a cylindrical duodenum, also accompanied by hepatic vessels, but of narrower dimensions; 4*th*, a short and muscular rectum.

All the Diptera dissected by M. Dufour were provided with salivary glands, a character which that accurate observer regards as being common to all insects furnished with a sucker. The structure, however, of those parts varies according to the genus.[8] They no doubt serve to increase the fluidity of the nutritive juices absorbed by the sucker. We may add, that both Dufour and Dutrochet have observed that the stomach of many Diptera is accompanied by a kind of paunch, in which a portion of the aliments is deposited.

Many tribes of this extensive order, if not decidedly noxious, at least occasion us great annoyance, not only by sucking our own blood, but by laying their eggs on the bodies of our living domestic animals, and on whatever uncooked fleshy viands they can attain to, especially during sultry weather, when the process of corruption is the most speedy, and the insects themselves are in their prime of strength and vigour. On the other hand, they may be regarded as serviceable, on account of the rapid consumption, by their most gluttonous larvæ, of all animal and several vegetable substances in a state of putridity. Their term of life in the perfect state is but of short duration. A few months or even weeks elapse, and their merry course is run. Such as contrive to fight their way to the conclusion of the ambiguous autumn, perish on the first approach of frost. A few half-benumbed house-flies indeed are generally seen in our apartments till Christmas time; and the delusive gleam of a sunny winter day not seldom re-animates their feeble forms so far as to produce a dubious buzz about our windows; but such as show themselves in open places are speedily snapped up by redbreasts and other feathered epicures, greedy of insect food at that unaccustomed season; and it is probable that few survive till spring. As their eggs, however, are generally deposited in a putrescent nidus, adapted to the propensities of the incipient young; and as that nidus is not of a nature to remain for a length of time unconsumed, it may be fairly inferred that our summer swarms are produced originally from a few individuals, which in some snug corner have survived the most inclement season of the year, and are not the result (as happens in the case of many lepidopterous kinds) of eggs which have been laid during the preceding autumn. It is possible that such as assume the pupa state towards the close of summer under ground, may rest secure in that condition, till called into their winged existence by the returning warmth of the enlivening spring.

---

All these insects undergo a complete metamorphosis, and are remarkable in this, that the larvæ do not change their skins except at the period of their passing into the nympha state. Some form a kind of cocoon; but others remain uncovered, and can scarcely be even said to change their skin, which seems to harden over them, so as to form an egg-like case for the enclosed pupa. Dipterous larvæ are apodal or without feet, although some which belong to the family Nemocera of Lat. are provided with appendages which serve the same purpose. The head is sometimes projected and constant in its form, sometimes variable in figure, capable of being withdrawn into the body, and undistinguishable from the other segments except by its anterior position, and the existence of the parts of the mouth. This soft and changeable form of the head is, we conceive, peculiar to the larvæ of the present order. It is generally furnished with one or two retractile hooks, and some nipple-like projections. The principal orifices of respiration are almost always placed at the posterior extremity; and in many species there is also a pair of stigmatic openings on the segment next the head. Such as dwell in water, or inhabit corrupt and fluid matters, have their bodies terminated posteriorly by a tail-like prolongation, susceptible of being lengthened or withdrawn according to circumstances, and ending in a radiated expansion, which communicates with internal tracheæ. There are few pieces of natural mechanism so ingenious and admirable as the respiratory systems of the rat-tailed worm, and of the larvæ of gnats and other aquatic Diptera.

We have already alluded to the peculiar transformation of these insects. The skin of the larva seems to harden over and enclose the nymph. The body of the contained insect first detaches itself to a certain extent from the outer skin, leaving on its inner surface the exuviæ of its external organs. In its early state it presents only a soft or gelatinous mass, without distinct characters; but after a time the parts of the perfect insect begin to be developed, and it finally escapes from its prison by butting with its head against the upper part of the case, which ere long opens as it were upon a hinge, like the lid of a cylindrical snuff-box.

The general characteristics of this order are obvious to the eye of an ordinary observer, and are designated in the works even of the most ancient naturalists. Yet Fabricius, by placing with the Diptera certain Arachnides, and the parasitical species of the genus Pediculus, falsified the essential nature of the order. It cannot be denied, however, that here, as in all other great natural groups, there are anomalous or aberrant genera, which depart in a great measure from the ordinary conditions of their kind. Thus, among the pupiparous tribes, the wings, the balancers, and the usual sheath of the sucker, show a tendency to disappear in many species; and in *Nycteribia* and *Melophagus* the organs of flight are entirely wanting.[1]

DIVISION I.—PROBOSCIDEÆ.

The apex of the proboscis with a fleshy labium, and the haustellum covered by a horny labrum; before these are placed two jointed palpi.

A. The antennæ consisting of many joints.

FAMILY I.—TIPULARIÆ.

Antennæ extended forwards, consisting of six or more distinct joints. Palpi standing out, jointed. Halteres naked. Abdomen with seven or eight segments.

a. Culiciformes.

Eyes lunate: ocelli wanting: antennæ of the males plumose, of the females pubescent: mouth not elongate: palpi five-jointed: thorax without a cross suture: abdomen consisting of eight segments.

*

Proboscis extending forwards, longer than the antennæ; palpi straight; wings with the nervures and margin covered with scales.

Genus Culex, Linn. Antennæ porrect, or extending forwards, filiform, fourteen-jointed; plumose in the male, pilose in the female; palpi porrect, five-jointed, longer than the proboscis in the male, very short in the female; proboscis porrect, the length of the thorax: wings scaly, incumbent. Meig. *Zw.* pl. i. fig. 1–10.

The species of this and of some nearly allied genera are extremely troublesome towards evening, especially in the neighbourhood of moist or marshy places. They are greedy of blood, and under the well-known names of Gnats, Mosquitoes, &c. they persecute man and beast, not only sucking our "life-stream," but instilling a poison which, though feeble from its minute quantity, yet often produces pain and inflammation. Although abundant in Italy and all the warmer countries of the earth, they are nowhere more troublesome than amid the barren wastes of Lapland. They feed also on vegetable juices. The female deposits her eggs in the water to the amount of several hundreds, and the larvæ are consequently very frequent in all stagnant pools in spring and summer, where they may be seen when undisturbed, suspended from the surface, with their heads downwards. At this time they breathe by the caudal extremity; but in the nympha state, during which they are still aquatic, the respiratory organs are placed upon the thorax. On assuming the perfect state, the light exuviæ of the nymph serve as a support, by means of which the imago sustains itself for a time on the surface of the waters. The whole of these transformations are passed through in the course of three or four weeks. It is said that the females alone annoy us as blood-suckers. Their

[1] The principal works on this order are, Fallen's *Diptera Suecica*, 4to, 1814–17; Meigen's *Systematische beschreibung der bekannten Europaischen Zweiflugeligen Insecten*, 8vo, 1818–1830 (by this work we are guided in the ensuing portion of our article); Wiedeman's *Diptera Exotica*, 8vo, 1821; and Macquart's *Insectes Diptères du Nord de la France*, 8vo, 1826–9, published in the *Mém. de la Soc. Royale*, &c. de Lille.

Diptera Proboscideæ.

shrill nocturnal pipe, the prelude to a closer contact, is particularly distressing in many continental countries, especially to an inexperienced traveller, unprovided with a *cousinière* or mosquito curtain. The Laplanders defend themselves by means of smoke and grease.

C. *pipiens.* Palpi and antennæ dark brown: thorax rufous, nearly rust colour, with two brown longitudinal lines: abdomen ringed with whitish grey and dark brown: halteres whitish: wings unspotted: legs pale brownish, the base of the thighs yellowish; the apex of the tibiæ with a small spot of changeable white. Length three lines. Fab. Linn. Réaumur. Wood's *Illus. of Linn. Genera of Insects*, pl. xcvii. Common in almost all countries.

Genus Anopheles, Meigen. Antennæ porrect, filiform, fourteen-jointed; plumose in the male, pilose in the female: palpi porrect, five-jointed, the length of the proboscis: proboscis porrect, the length of the thorax: wings scaly, incumbent. Meig. *Zw.* i. 10, pl. i. f. 11–17; Curtis, *Brit. Ent.* v. pl. ccx.

A. *bifurcatus.* Plume of the antennæ brownish grey in the males: the two terminal joints of the palpi forming a flat club; circle round the eyes white: thorax ash grey, with a dark-brown line on the sides, and three others down the middle: abdomen grey, ringed with brown: legs brown, the thighs yellowish: halteres dirty white; wings unspotted. The colour of the female is yellowish brown. Three and a half lines. Curtis, *l. c.* *Culex bifurcatus*, Linn. According to Linnæus, the larva, like those of the preceding genus, reside in the water, and the perfect insect does not bite. Only one other species is described by Meigen, which is distinguished by having five dusky spots on each wing. Two others are described in the third volume of the *Zoological Journal.*

Genus Ædes, Hoffmgg. Antennæ porrect, filiform, fourteen-jointed; plumose in the male, pilose in the female: proboscis porrect, as long as the thorax: palpi very short: wings scaly, incumbent. Meig. *Zw.* i. 13.

Æ. *cinereus.* Greyish brown: thorax reddish, pubescent: wings unspotted: thighs rather paler than the other parts of the leg: palpi very short, in other respects not differing much from Culex. Two to two and a half lines. Apparently a rare and imperfectly known insect.

* *

Proboscis shorter than the antennæ; palpi incurved.

Genus Corethra, Meig. Named from the Greek word *κόϱηθϱον, a brush*, with reference to the appearance of the antennæ. Antennæ porrect, filiform, fourteen-jointed; verticillately plumose in the male, pilose in the female: palpi standing out, incurved, four-jointed, the first joint shortest: wings incumbent, the nervures villose, and the hinder margin ciliated with scales. Meig. *Zw.* i. 14, pl. i. f. 18–23.

C. *pallida.* Whitish: plume of the antennæ brown; eyes black: thorax with three pale-brown abbreviated lines: thighs and tibiæ white, spotted with black; the joints of the tarsi somewhat brownish: wings hyaline, with an obsolete brownish shade over the middle. Male two and a half, female two lines. Meig. *Zw.* vol. i. pl. i. fig. 23, *female.* Found on the continent of Europe. *C. plumicornis* and *culiciformis* inhabit Britain, and have been described, with their usual felicity, by Réaumur and Degeer. Their larvæ differ from those of Culex in their usually horizontal posture. That of *C. plumicornis* is remarkable for its translucent texture, which renders it almost invisible. It was hence called *Tipula cristallina* by Degeer.

Genus Chironomus, Meig. (Plate CCXXXVIII. fig. 1). Antennæ porrect, filiform, in the male plumose, thirteen-jointed; the terminal joint very long (ibid. fig. 1, *a*); in the female six-jointed, pilose; palpi standing out, incurved, four-jointed; wings lanceolate, deflexed. Meig. *Zw.* i. 18, pl. ii. f. 1–7.

C. *elegans.* Head light yellow; plume of the male antennæ brown; female antennæ pale yellow, the terminal joint brown; thorax hood-shaped in front, elongate, sulphur-yellow, with fulvous vittæ, and having three black spots on each side in the form of a triangle, towards the base of the wings; abdomen sulphur-yellow; legs fulvous, thick, with black joints and a ring of the same colour in the centre of the middle and hinder tibiæ; anterior tarsi not elongate; wings white, with three black points not far from the hinder margin, one towards the middle, and two others near each other, towards the apex. Three to three and a half lines. Meig. *Zw.* vol. i. pl. ii. f. 7, *female.* This rare species, represented by the figures last referred to, has been taken lately at Raehills in Dumfriesshire. We believe it to have been previously unknown in Britain. The genus is very extensive, comprehending little short of a hundred species, the greater portion of which inhabit Britain. The little pink-coloured tortuous worm, frequent in water-barrels, is the larva of *Chironomus plumosus.*

Genus Tanypus, Meig.; named from *τανυω, to stretch out*, and *πους, the foot.* Antennæ porrect, filiform, fourteen-jointed; in the male plumose, with the twelve lowest joints globose, the thirteenth very long, the terminal short and acute; in the female pilose, all the joints globose, the terminal thickest; palpi standing out, incurved, four-jointed, the basal joint shortest; ocelli wanting; wings lanceolate, deflexed, pilose. Meig. *Zw.* i. 55, pl. ii. f. 8–12.

T. *varius.* Male. Antennæ and palpi brown; head and thorax grey, the lines on the latter dark brown, with a grey play of colour in the middle; abdomen yellowish, banded with brown, and having a blackish line on the back; legs brownish yellow, the knee and apex of the tibiæ brown; halteres white; wings with an oblique grey cloud before the apex, having two dark-brown spots in it near the anterior border, and three smaller dark spots at the hinder margin; there is a grey spot at the apex of the wing, and near the middle a rather broad band, in the anterior part of which are placed three blackish spots, two behind each other, and the third, which is smaller, beneath, forming a triangle. The female is of a yellower hue than the male, and the marks on the back, as well as the bands on the abdomen, are paler; the wings are marked in a similar manner. Male three to three and a half, female two to two and a half lines. Meig. *Zw.* i. pl. ii. fig. 12, *male.* Frequents banks and hedges, but is not common. It occurs near London, and in some other parts of England.

The *Tipula maculata*, of which the history is given by Degeer, belongs to this genus. Twelve species are described by Benoit Frederick Fries, in his *Monograph* of the Swedish Tanypi. His work is enriched by some new historical details. Above twenty species occur in Britain.

Genus Ceratopogon, Meig. The generic name is derived from *κεϱας, a horn*, and *πωγον, a beard.* Antennæ porrect, filiform, thirteen-jointed, the eight lowest joints globose (bearded externally in the male), the following cylindrical, elongate; palpi porrect, incurved, four-jointed, the joints unequal; ocelli wanting; wings parallel, incumbent. Meig. *Zw.* i. 68, pl. ii. f. 13–18.

The larvæ of these insects differ from those of most of their congeners in not being aquatic. They inhabit vegetable galls. The species are numerous, and of small dimensions. Meigen describes forty-five different kinds, of which about one half have been detected in Britain.

C. *bipunctatus.* Black; the antennæ, including the brush of the males, dark brown; thorax clothed with fine yellow pubescence; halteres white; wings thickly covered

Diptera Proboscideæ.

with grey pubescence, and having a whitish spot in the middle of the anterior margin; legs pitch-brown; tibiæ with long hairs externally; pubescence of the tarsi white. One line. *Tipula bipunctata*, Linn.; *Forcipomyia pictipennis*, Megerle; *Labidomyia bipunctata*, Stephens. Inhabits England and various parts of the continent.

GENUS MACROPEZA, Meig. So named from *μακρος*, *long*, and *πεζα*, *the foot*, the hinder legs being remarkable for their length. Antennæ porrect, filiform, fourteen-jointed; the joints cylindric, the five last longest: wings lanceolate, elongate; hinder legs very long. Meig. *Zw.* i. 87, pl. iii. f. 1, 2.

M. *albitarsis*. Head black, with a broad forehead without ocelli; thorax cinereous, with three narrow black lines, the central one widest; sides of the thorax and shoulders black; scutellum cinereous; abdomen black; halteres white; wings hyaline, with pale-brown nervures; legs black, the tarsi whitish; the hinder legs uncommonly long, particularly the tarsi, which are as long as the thighs and tibiæ united. Length one and a third. Length of the wing two and two thirds, of the hinder legs four lines. Pl. iii. f. 1, *female*. The female only of this singular insect appears to be known: it has not occurred in Britain.

b. Gallicolæ.

Eyes lunate: antennæ with hairs disposed in whirls; palpi incurved; wings pubescent, obtuse, with two or three longitudinal nervures; tibiæ without spurs at the end.

GENUS LASIOPTERA, Meig. The name is from *λασιος*, *hirsute*, and *πτερα*, *wings*. Antennæ porrect, filiform, consisting of many joints, which are globose and hairy; ocelli wanting: wings incumbent, villose, with two nervures. Meig. *Zw.* i. 88, pl. iii. f. 3–5.

L. *picta*. Female. Antennæ black, shorter than the thorax, cylindrical, twenty-four jointed; the joints nearly globose and pubescent: thorax black; abdomen black, margined with white, and having two triangular white spots on each segment: thighs yellow; tibiæ and tarsal joints white, with the apex black: halteres white: wings ash-grey, having a narrow black edge anteriorly, in which there is a white spot. One line. Meig. *Zw.* i. pl. iii. fig. 3, *female*. *Diomyza Juniperi*, Megerle.

Occurs on the continent of Europe, but is rare.

GENUS CECIDOMYIA, Latreille. Antennæ projecting, moniliform, many jointed, the joints remote from each other: ocelli wanting; first joint of the tarsi very short: wings incumbent, villose, with three nervures. Meig. *Zw.* i. 93, pl. iii. fig. 8–12.

C. *palustris*. Thorax pale, with three broad black vittæ: abdomen flesh-red; the halteres white. *Tipula palustris*, Fab. Linn. Not unfrequent in Britain and elsewhere. We have nearly thirty indigenous species, among which *C. tritici*, commonly called the *wheat-fly*, is an object of great interest to the agriculturist.[1]

GENUS CAMPYLOMYZA, Wied. Antennæ projecting, cylindrical, fourteen-jointed, the two radical joints thickened: ocelli three: wings pilose, with three nervures. Meig. *Zw.* i. pl. iii. fig. 6–7.

C. *bicolor*. Female. Antennæ dark brown: head and thorax black, somewhat shining: abdomen dark brown, with pale incisures: halteres white: legs testaceous: wings hyaline. Half a line in length.

Found in April and May in hedges, not common.

c. Noctuæformes.

Eyes lunate: ocelli wanting: antennæ moniliform, with a seta at the base: wings broad, villose, with numerous longitudinal nervures, but without cross nerves: tibiæ without spurs.

GENUS PSYCHODA, Lat. (Plate CCXXXVIII. figs. 2 and 2 *a*). Antennæ projecting, moniliform, pilose, many jointed, the two radical joints thick, the remainder globose, and remote from each other: palpi standing out, four jointed, the joints equal: ocelli wanting: wings broad, lanceolate, villose, without transverse nerves. Meig. *Zw.* i. pl. iii. fig. 13–18.

P. *palustris*. Head, thorax, and abdomen covered with white wool-like hairs: wings black at the apex, the centre with a dark-brown band, which forms an acute angle in the middle, the base shaded with brown; fringe dark brown, white at the apex of the wing: halteres dark brown: legs white; apex of the tibiæ and the two last tarsal joints black. Two lines. Meig. *Zw.* i. pl. iii. fig. 18. Found in Britain occasionally, along with above a dozen other species. We know little of the habits or metamorphoses of these insects. They occur in moist and impure, as well as in marshy places.

d. Rostratæ.

Eyes somewhat rounded, separated on the forehead; ocelli wanting: head elongated into a rostrum anteriorly: palpi incurved: thorax with an arched suture across the middle: abdomen eight-ringed: tibiæ more or less spurred.

GENUS ERIOPTERA, Meig. From *ειρος*, *wool*, and *πτερα*, *wings*. Antennæ projecting, setiform, sixteen-jointed, the first joint cylindrical, second cup-shaped, the following ovate: ocelli wanting: palpi standing out, incurved, cylindrical, four-jointed, the joints equal: intermediate legs shorter than the others: wings incumbent, parallel, the nervures villose.

E. *maculata*. Dirty yellow, as well as the antennæ and legs: thighs brown at the apex, and having a brown ring in the middle: palpi brown; the abdomen with a brown line along the back: wings with pale nerves and ferruginous ocellated spots, which are partly single and partly form a macular band. Two and a half lines. Inhabits Britain and the continent of Europe. We have about thirty ascertained indigenous species.[2]

GENUS LIMNOBIA, Meig. From *λιμνη*, *a marsh*, and *βιοω*, *I live*. Antennæ projecting, setiform, the joints from fifteen to seventeen, the radical joint cylindrical, second cup-shaped, the remainder oblong or globose: palpi standing out, incurved, cylindrical, four-jointed, the joints equal: ocelli wanting: wings generally incumbent and parallel, the nervures naked. Meig. *Zw.* i. pl. iv. v. vi.

L. *rivosa*. Antennæ as long as the head, setiform, reddish brown; palpi of a similar colour: head grey; the forehead with a small protuberance behind the antennæ: thorax light grey, with reddish-brown vittæ; scutellum yellowish; metathorax bright grey: abdomen light grey inclining to red, with a reddish-brown line on the back, which is waved on the sides, and has a grey play of colour in the middle: legs rather thick, testaceous, the thighs darker: halteres yellow: wings clear hyaline, having a testaceous streak along the anterior margin; not far from the base another streak leaves the marginal one and runs along the third longitudinal nerve, and from this a third runs along the cross nerves, forming an obtuse angle; the anterior streak has a semicircular projection near the middle, and just behind the base there is a transparent marginal streak with a black spot. From twelve to thirteen lines. *Tipula rivosa*, Linn.; *Tipula triangularis*, Degeer; *Pedicia rivosa*, Lat.

Rare on the continent. In Scotland we lately observed it in considerable numbers in several of the northern counties, frequenting marshy glades by the sides of rivers. It likewise occurs in the vicinity of Edinburgh. The genus Limnobia is rather extensive, containing upwards of sixty European species, the greater proportion of which are indigenous to Britain. Degeer has published some curious details regarding the manners and metamorphoses of *L. replicata.*[1]

---

[1] See *Linn. Trans.* iv. 230, and v. 106.

[2] The genus is named *Eriopteryx* by Mr Stephens—a commendable change, in as much as it avoids a termination characteristic of the *ordinal* rather than the *generic* groups of Entomology.

Genus Rhipidia, Meig. Antennæ projecting, fourteen-jointed, the radical joint cylindrical, second and third cup-shaped, the following globose, remote, pectinated on two sides in the male: palpi standing out, incurved, cylindrical, four-jointed, the joints nearly equal: ocelli wanting: wings incumbent, parallel. Meig. *Zw.* i. pl. v. fig. 9–11.

R. *maculata.* Forehead light grey; palpi and antennæ brown, the latter twice the length of the head: thorax bright grey, with a brown vitta, which has an indistinct brown line close to it on each side behind: abdomen dark brown: halteres pale yellow: legs long, thin, brownish yellow; the apex of the thighs, the tibiæ, and the tarsi, brown: wings hyaline, the surface sprinkled with pale brown spots, some of which at the anterior border are larger and darker, and the cross nerve is margined with brown. Three lines. Meig. *Zw.* i. pl. v. fig. 11, *male.* Inhabits England, Germany, &c.

Genus Ctenophora, Meig. Antennæ projecting, thirteen-jointed, the radical joint cylindrical, second globose, third oblong, the following pectinated in the male, in the female simple, globose or ovate: palpi standing out, incurved, cylindrical, four-jointed, the terminal joint elongate: ocelli wanting: wings spreading, shining.

C. *bimaculata.* Head black: palpi rufous beneath, brown above: antennæ dark brown, the joints globular in the female: thorax and abdomen black; the latter in the female marbled on the sides and belly with rufous, which sometimes runs into orange-yellow, spots; the abdomen of both sexes has a greyish transverse spot at the base: halteres and legs rufous; the apex of the thighs, the tibiæ, and the tarsi dark brown: wings hyaline, the anterior margin yellow, having a dark-brown band, extending half way across, and the apex of the same colour. Male six, female from seven to eight lines. *Tipula bimaculata*, Linn. Found in Britain, with six other species belonging to the same genus.

Genus Tipula, Linn. (Plate CCXXXVIII. figs. 3 and 3 *a.*) Antennæ projecting, thirteen-jointed, the radical joint cylindrical, second cup-shaped, the following cylindrical and pilose: palpi standing out, incurved, cylindrical, four-jointed,[2] the terminal joint elongate: ocelli wanting: wings lanceolate, spreading.

T. *oleracea.* Palpi and antennæ dark brown, the two lowest joints of the latter yellowish grey; forehead bright grey, with a reddish-brown line; the snout yellowish brown: thorax bright grey, having a testaceous dorsal line bounded with dusky; metathorax whitish grey: abdomen testaceous, with a dusky line on the back, which is scarcely perceptible; thighs and tibiæ testaceous, the apex and the tarsi dark brown: halteres brown: wings pale brown, the anterior margin bordered with testaceous, but not to the apex; behind this border there is a whitish streak. Eleven lines. Linn. Fab. Degeer, Lat. This species is common in meadows. It is known in England by the title of *Harry Long-legs*, and is called *Jenny Nettles* in Scotland. The genus Tipula, considered in relation to Europe, contains forty-four species, several of which are large and conspicuous insects, and many of them are very plentiful. *T. crocata*, of a deep velvet black with yellow bands, is a very ornamental species. We have taken it near Edinburgh.

Genus Nephrotoma, Meig. Antennæ projecting, in the male nineteen-jointed, with the first and third joints cylindrical, second cup-shaped, the following excised; in the female fifteen-jointed, the first and third joints cylindrical, second cup-shaped, the following somewhat cylindrical, thickened at the base: palpi standing out, incurved, four jointed, the terminal joints elongate: ocelli wanting: wings lanceolate, spreading. Meig. i. pl. v. f. 19–22.

N. *dorsalis.* Antennæ with the first and second joints ferruginous, the rest black: ground-colour reddish yellow; the forehead with a black vitta: thorax with three shining black lines; the sides of the breast unspotted: scutellum with a black spot; metathorax marked with a black line, and the hinder margin of the same colour: abdomen with a black dorsal line, and a longitudinal line of the same colour on the sides and belly: thighs and tibiæ ferruginous, the apex brown: tarsi dark brown: halteres yellow: wings nearly hyaline, slightly clouded with brownish yellow, the stigma dark brown: the apex of the wing is likewise brownish. Male five and a half, female seven lines. Found in hedges during summer, but is not common. It has occurred in the vicinity of London.

Genus Ptychoptera, Meig. Antennæ projecting, sixteen-jointed, the radical joint short and cylindrical, second cup-shaped, third long and cylindrical, the following oblong: palpi standing out, incurved, elongate, four-jointed, the first joint shortest, second and third long, and of equal length, the fourth very long, setaceous: ocelli wanting: wings spreading, plicate at the hinder margin.

P. *contaminata.* The prevailing colour is shining black: palpi ferruginous: antennæ dark brown: the sides of the breast silky grey: scutellum testaceous: abdomen of the male with two ferruginous bands, that of the female with two ferruginous spots on both sides: legs rufous: the apex of the thighs, the tibiæ, and the tarsi, dark brown: halteres rufous, the knob brownish at the tip: wings nearly hyaline; near the middle of the anterior border is a dark-brown abbreviated band; between this and the apex there is a brown marginal spot, and two or three others at the anterior margin. Male three and a half, female five lines. *Tipula contaminata*, Linn. Fab. Lat. Not rare during summer in Britain and other parts of Europe.

Genus Nematocera, Meig. Antennæ projecting, filiform, six-jointed, the radical joints cylindric, second cup-shaped, the following cylindrical, equal: ocelli wanting: palpi standing out, incurved, four-jointed, the joints equal.

N. *bicolor.* Head ash-grey; forehead wide, brighter at the eyes: thorax bright grey, with three dark lines on the back, that next the side short: abdomen flat, dark brown: legs of the same colour, the base of the thighs, and likewise the halteres, yellow: wings rather dull, without a stigma. Five lines. Meig. *Zw.* i. pl. vi. fig. 1.

Seemingly rare: we are unacquainted with its native country. The specimens from which Meigen took his description were preserved in the collection of M. Baumhauer.

Genus Anisomera, Hoff. Antennæ projecting, setaceous, six-jointed, the radical joint cylindrical, second cup-shaped, third very long: ocelli wanting.

A. *obscura.* Antennæ brown: the prevailing colour of the body brownish grey; thorax with three wide dark

---

[1] *Memoires*, t. vi. plate 20.

[2] Latreille says, "de cinq articles,"—but he counts the radical tubercle, which does not seem to have been regarded in Meigen's enumeration.

lines: along the abdomen of the males, which is nearly hoary, runs a narrow vitta, and on the under side of the first segment there is a broad yellow spot, and a smaller one on the second; wings brownish yellow, especially at the cross nerves; legs yellowish brown; the apex of the thighs dark; the anterior thighs thicker and shorter than the others. Four lines. Meig. *Zw.* i. pl. vii. fig. 5, *male.* Found in Germany, Portugal, and England. In the latter country another species has occurred, which has been named *A. lucidipennis.*

Genus Trichocera, Meig.; from τριξ, *hair*, and κερας, *a horn.* Antennæ projecting, setiform, the two lower joints thickened, the remainder oblong and pubescent; palpi standing out, incurved, cylindrical, five-jointed, the joints nearly equal: wings incumbent.

T. *hiemalis.* Palpi, antennæ, and legs, dark brown: head grey: thorax greyish, with four distinct brown vittæ, the hinder part unspotted: abdomen wholly dark brown passing into grey; the caudal process in the female shining black: halteres pale yellow, with a brown knob: wings pale grey or somewhat brownish, unspotted. Two and a half lines. *Limonia hiemalis,* Lat. Abundant in October and November, and usually found throughout the winter. Another British species, *T. regelationis,* is also often seen on walls and houses, even during that inclement season.

e. Fungicolæ.

Eyes round or oblong, separated on the forehead: ocelli unequal, sometimes wanting. Palpi incurved, four-jointed: thorax without a cross suture: abdomen seven-ringed: coxæ long: tibiæ spurred.

*

Antennæ setiform, with indistinct joints, the two lower ones thickened.

Genus Dixa, Meig. Antennæ projecting, setiform, the two lowest joints thickened, the rest pubescent: palpi standing out, incurved, cylindrical, four-jointed, the first joint very short: ocelli wanting: wings incumbent, parallel.

D. *aprilina.* Palpi and antennæ dark brown: head brownish yellow, with a large blackish heart-shaped spot on the forehead: thorax light yellow, passing into brown, and marked with three dark lines: abdomen dark brown: halteres yellowish, with a brown knob: legs brownish yellow; apex of the thighs, of the tibiæ, and the tarsi, dark brown: wings hyaline, somewhat whitish, with brown nerves. Two lines. Meig. *Zw.* i. pl. vii. fig. 12, *male.* Found on the continent and in Britain. Meigen describes four species, two of which occur in this country, which also produces a third, named *D. variegata* by Mr Stephens.

Genus Bolitophila, Hoff. Antennæ long, setiform, projecting forwards, the two radical joints thick: ocelli three, placed on the forehead in a transverse line: wings incumbent, parallel, obtuse.

B. *fusca.* Head yellowish, with dark-brown antennæ: thorax yellowish, with three brownish lines on the back: abdomen, halteres, and legs, dark brown; basal half of the thighs yellow, which gradually passes into brown: wings somewhat greyish, with a brown spot at the stigma. Two to two and a half lines. English examples of this species are preserved in the British Museum. According to Mr Curtis, two other kinds inhabit Britain; viz. *B. maculipennis* and *B. cinerea;* the former of these does not appear to be known to continental naturalists. M. Guerin has published a complete and detailed history of a species of this genus, of which the larva lives in mushrooms.[1]

Genus Macrocera, Meig.; named from μακρος, *large,* and κερας, *a horn*—the antennæ being of unusual length. Antennæ projecting, setiform, long, the two radical joints thick: ocelli three, placed on the forehead in the form of a triangle: wings obtuse, incumbent, parallel.

M. *lutea.* Of a uniform ochre-yellow: antennæ above twice the length of the body, brown, yellow at the base: abdomen inclining to brown behind: legs yellow, with brown tarsi. Three lines. This species occurs in the south of England, and eight others are recorded as indigenous to Britain.

* *

Antennæ compressed, sixteen-jointed.

Genus Synapha, Meig. Antennæ projecting, cylindrical, sixteen-jointed? the two lowest joints distinct: eyes rounded: ocelli three, unequal, placed in a line on the forehead: tibiæ unarmed on the sides.

S. *fasciata.* Head and antennæ black: palpi ferruginous: thorax pubescent, shining black; scutellum of a similar colour, small: first four joints of the abdomen shining red, with a black band across their hinder margin, the remainder black: thighs and tibiæ ferruginous, tarsi brown: wings hyaline, the central longitudinal nerve forming an oblong cell behind the cross nerve. One and a half line. Inhabits Germany, but is rare.

Genus Mycetobia, Meig. Antennæ projecting, cylindrical, sixteen-jointed, the two radical joints distinct: eyes kidney-shaped: ocelli three, unequal, approximating, placed on the forehead in the form of a triangle: tibiæ unarmed on the sides.

M. *pullipes.* Black: palpi yellow: antennæ brown, nearly cylindrical, and about the length of the thorax; the latter somewhat pubescent: abdomen rather depressed: halteres and legs bright yellow, the tarsi passing into brown at the apex: wings large, rounded at the apex: and having brownish-black nervures. One and a half line. Occurs in the vicinity of London, and in some other parts of Britain.

Genus Platyura, Meig. Name derived from πλατυς, *broad,* and ουρα, *the tail.* Antennæ projecting, compressed, sixteen-jointed, the two radical joints distinct: eyes rounded: ocelli three, approximating, unequal, placed on the forehead in the form of a triangle: tibiæ unarmed on the sides: abdomen depressed behind.

P. *semirufa.* Head, antennæ, and thorax black; the latter with a narrow arched line of white anteriorly: abdomen yellowish red, passing into brown, the two first segments black: halteres and legs rufous, the tarsi brown: wings nearly hyaline, without spots or bands. Three lines. Found near London, Edinburgh, and in the border counties of Scotland Thirteen other species are natives of Britain.

Genus Gnoriste, Hoff. Antennæ projecting, cylindrical, sixteen-jointed, the two radical joints thick and short: proboscis elongate, bearing the palpi at the apex: ocelli three, unequal, placed on the forehead in the form of a triangle: tibiæ spurred at the apex, the sides spinose.

G. *apicalis.* Head black; antennæ dark brown: proboscis twice the length of the head; the palpi, which are inserted near the apex, small and ferruginous: thorax black, impressed with two deep longitudinal lines, which become obsolete behind the middle: abdomen dark brown, pubescent: halteres yellow: coxæ elongate, the anterior pair ferruginous, the others black: thighs and tibiæ yellow, the tarsi dark brown: wings somewhat clouded, the apex brown. Five lines. Has been found in Prussia, but is rare.

Genus Sciophila, Hoff. Antennæ projecting, somewhat compressed, sixteen-jointed, the two radical joints distinct: ocelli three, unequal, approximating, placed on the forehead in the form of a triangle: tibiæ with spurs at the apex, and spines on the sides: wings with the intermediate cell small and nearly quadrate.

---

[1] *Annales des Sciences Nat.* t. x.

S. *fimbriata.* Ferruginous; antennæ brown, yellow at the base; anterior part of the head yellow, the forehead brown: thighs ferruginous, tibiæ and tarsi brown: abdomen pubescent, the segments margined behind with black, the hinder extremity likewise black: wings unspotted, hyaline. One two-thirds. This insect, and seven other species of the genus, occur in Britain.

Genus Leia, Meig.; named from λειος, *smooth.* Antennæ projecting, compressed, sixteen-jointed, the two radical joints distinct: eyes oblong: ocelli three, unequal: tibiæ with spurs at the apex, the hinder ones spinous on the sides.

L. *flavicornis.* Ochraceous, as well as the antennæ: ocelli remote: thorax and abdomen somewhat shining: tarsi brown: wings slightly yellowish, with a narrow, somewhat arched, cross band of brown before the apex, slightly increasing in width at the anterior border; and towards the hinder margin of the wing there is a small pale-brown spot placed at the hindermost longitudinal nerve. Two lines. Meig. *Zw.* i. pl. ix. fig. 11, *female.* Inhabits Britain, with four others of the ten described by Meigen as occurring in Europe.

Genus Mycetophila, Meig. Antennæ projecting, compressed, sixteen-jointed, the two radical joints distinct: eyes oblong: ocelli indistinct: tibiæ with spurs at the apex, the hinder ones with spines on the sides.

M. *lineola.* Hypostoma[1] and palpi yellow; antennæ greyish brown, the two radical joints yellow: thorax ochreous above, with three brown lines, the sides of the breast with a mixture of grey: abdomen brown, with yellow incisures: halteres yellow: legs pale yellow, the tarsi brown; hinder thighs black at the apex: wings yellowish, somewhat dusky along the anterior border, and marked with a dark-brown spot near the middle. Two lines. Meig. *Zw.* i. pl. ix. fig. 15. This species occurs in Roxburghshire, near London, and on the continent of Europe. The genus contains thirty species; of these upwards of twenty are included in the entomological catalogues of Britain. The larvæ of several species are found in great numbers in fungi, on the substance of which they feed. The *M. fusca* of Lat. and Meigen seems indeed to have been described by Degeer under the name of *Tipula fungorum.*[2]

Genus Cordyla, Meig. Antennæ projecting, twelve-jointed, the two radical joints distinct: eyes rounded; ocelli wanting: tibiæ with spurs at the apex, but unarmed on the sides.

C. *crassicornis.* Head blackish; antennæ twice the length of the head, compressed when seen from the side, the colour dark brown: thorax grey, the back darker in the middle: abdomen dark brown: halteres and legs bright yellow, the hinder thighs brown at the apex; tarsi brown: wings grey. One and a half. Meig. *Zw.* i. pl. x. fig. 1. Inhabits Austria, England, &c.

f. Lugubri.

Eyes nearly meeting above, and deeply margined: ocelli unequal: antennæ cylindrical: palpi three-jointed: thorax without cross suture: abdomen seven-ringed.

Genus Sciara, Meig. Antennæ porrect, cylindric, pubescent, sixteen-jointed; the two basal joints thickest: eyes deeply emarginate: ocelli unequal: palpi exserted, incurved, three-jointed: wings incumbent, parallel.

S. *Thomæ.* Black; abdomen with a longitudinal line of saffron yellow on each side, consisting of spots in the male, and narrower than in the female; the last has the incisures also yellow: wings smoke coloured, iridescent: halteres and legs piceous: thighs of the fore legs rufescent in both sexes. Four lines. *Tipula Thomæ,* Linn.; *Molobrus Thomæ,* Lat. Occurs at times in tolerable plenty in woods in the south of Scotland, and in many parts of England, generally frequenting umbelliferous plants, in the months of June, July, and August.

g. Latipennes.

Eyes of the male meeting above, those of the female separated and kidney-shaped; ocelli wanting: antennæ cylindrical: palpi four-jointed: proboscis porrect, perpendicular: abdomen eight-ringed: wings very broad.

Genus Simulia, Meig. Antennæ porrect, cylindric, eleven-jointed, the two basal joints distinct: palpi exserted, incurved, cylindric, four-jointed, the basal joint shortest: ocelli wanting: wings broad, incumbent, parallel.

S. *reptans.* Female. Palpi and antennæ brown; hypostoma white; forehead blackish blue; thorax brown, with a bluish play of colour, the anterior part cinereous, with a brown line in the middle, which has a cross streak of brown close to it on each side; the hinder part with an ash-grey play of colour: abdomen dark brown, with pale-yellow hairs at the base, the hinder segment shining bluish grey: thighs brown: tibiæ white, brown at the apex: anterior tarsi deep black, the medial and posterior tarsi brown: halteres pale yellow. One line. *Culex reptans,* Linn.; *Simulium reptans,* Lat. Of pretty frequent occurrence in Britain, and other countries. We have above a dozen indigenous species. These insects bite sharply, and attack various animals.

h. Muscæformes.

Eyes of the male meeting above, in the female separate and round: ocelli three, of equal size: antennæ cylindrical: thorax without a cross suture in the middle.

Genus Scatopse, Geoff. Antennæ projecting, cylindrical, perfoliate, eleven-jointed: eyes kidney-shaped: ocelli three: palpi concealed: legs unarmed.

S. *notata.* Shining black, smooth. The thorax has a white spot on the sides anteriorly: and there is another, crescent-shaped, before the base of the wing, and a similar crescent-shaped spot is placed on the sides at the base of the abdomen: halteres black. One and a third line. *Tipula notata,* Linn.; *Tip. latrinarum,* Degeer, vi. 160, pl. xxviii. p. 1–4; *Tipula albipennis,* Fab. Found in England, Scotland, Germany, &c.

The palpi in the preceding genus, as far as perceptible, seem to consist of only a single articulation—a character in which they differ from their congeners. The larvæ are apodal, and live in impure substances. The nymphs are naked and motionless. The perfect insects occur on the trunks of trees, on moist walls, and on flowers, especially those of the *Synantheræ,* of which they suck the nectaries. The species are few in number, and of small size.

Genus Penthetria, Meig. Antennæ projecting, cylindrical, perfoliate, eleven-jointed: eyes oval: ocelli three: palpi standing out, incurved, four jointed: legs unarmed.

P. *holosericea.* Entirely velvet-black, with brown eyes and wings: forehead of the males very narrow, that of the female wide; head in both sexes as wide as the thorax: wings of the male much smaller than those of the female: legs pubescent, without spines, much longer in the male than in the female. Male two and a half, female three and a half lines. Lat. *Gen. Crust.* iv. 267; Meig. *Zw.* i. pl. x. fig. 17, 18. Found in Germany, &c.

---

[1] This term is used by Meigen to designate the region of the head lying between the antennæ, the eyes, and the mouth. The same part is named *clypeus* by Fallen.

[2] *Mémoires,* t. vi. pl. 22. fig. 1–13.

Genus Dilophus, Meig.; from δις, *two*, and λοφος, *a comb*. Antennæ projecting, cylindrical, perfoliate, eleven-jointed: palpi standing out, incurved, five-jointed, the third joint dilated at the apex: anterior tibiæ radiated at the apex.

D. *vulgaris*. Shining black: wings of the males hyaline, with blackish marginal nerves; those of the female brown, with the apex hyaline, the nerves with a pale margin, and the stigma blackish. Two and a half lines. Meig. *Zw.* i. pl. xi. fig. 1, *male*. *Tipula febrilis*, Linn. Fab. Lat. Common during spring and summer.

Genus Bibio, Geoff. Antennæ projecting, cylindrical, perfoliate, nine-jointed; palpi incurved, cylindrical, five-jointed, first joint very short: ocelli three: anterior tibiæ mucronate at the apex. Meig. i. 309, pl. xi. f. 9–15; Curtis, *B. E.* pl. cxxxviii.

B. *Pomonæ*. Shining black, with pubescence of the same colour: thighs rufous: wings hyaline, the anterior margin fuscescent, marginal nervures and stigma dark brown. Male six, female seven lines. *Tipula Pomonæ*, Fab. Don. ix. 27, pl. ccc.

B. *Marci*. Very like the last, but entirely black; wings of the males hyaline, of the females brown; both have the anterior margin dark brown, with black-brown nervures, and a stigma of the same colour. Five to six lines. ♀ *Tipuli Marci*, Linn.; *Hirtea Marci*, Fab.; ♂ *Tip. brevicornis*, Linn. These two species, which are the largest of the genus, occur not unfrequently in Britain: in the south of Scotland the former is common, and we have often seen large *flocks* of the latter near Edinburgh.

In this genus the sexes differ considerably, which has not seldom led to the males and females being described as distinct species.[1] The larvæ are frequently found in the dung of cattle. They are apodal, but otherwise bear a resemblance to small caterpillars, being furnished with a few hairs directed backwards. They are also believed to change their skins before assuming the nympha state. The perfect insects appear in spring; and, according to the continental naturalists, at two different periods, corresponding to the feasts of St Mark and St John,—a circumstance which has obtained for them the names of *Mouches de St Marc* and *Mouches de St Jean*. Their flight is heavy, and they are sometimes seen in great quantities on fruit trees, to which, however, notwithstanding a vulgar prejudice to the contrary, they are in no way injurious. Meigen describes sixteen European species, and Mr Stephens enumerates fourteen as occurring in Britain. Their manners are curiously detailed by Réaumur.

Genus Aspistes, Hoff. Antennæ projecting, eight-jointed, the terminal joint thickened, ovate: ocelli three: anterior tibiæ terminating in a spine.

A. *berolinensis*. Antennæ black, somewhat longer than the thorax, the two lowest joints thickened at the apex, the following short, the terminal one broader, ovate, and excavated in the middle: thorax pitch-black, with an oval spot on the back anteriorly: abdomen pitch-black, pubescent, the hinder extremity brownish red: thighs nearly black; tibiæ and tarsi reddish yellow: wings hyaline, the marginal nervures dark brown, the others pale brown: halteres black. One line. Inhabits Germany, Prussia, &c. One or two other species are said to occur in Britain.

Genus Rhyphus, Lat. Antennæ projecting, subulate, sixteen-jointed, the two radical joints distinct: palpi exserted, incurved, four-jointed, the joints unequal, the second clavate: ocelli three, equal: legs unequal: wings parallel, incumbent.

R. *fuscatus*. Antennæ and palpi dark brown; head and thorax cinereous, the latter with three black lines, the central one longest: scutellum grey: abdomen of the males dark brown, with pale incisures, that of the female brownish yellow: halteres whitish: wings somewhat clouded, and having brown nervures, the stigma and a marginal spot fuscous. Male four, female three lines. Meig. *Zw.* i. pl. xi. fig. 18. ♀ Found in Britain, and is common in many parts of Europe.

B. Antennæ consisting of few joints.

FAMILY II.—XYLOPHAGI.

Antennæ projecting, approximating at the base, three-jointed, the third joint eight-ringed: proboscis retracted: ocelli three: abdomen composed of eight segments: halteres uncovered: wings parallel, incumbent; onychii three.

Genus Beris, Lat. (Plate CCXXXVIII. figs. 4 and 4 *a*.) Antennæ with the two radical joints short, third elongate, conical, eight-ringed: scutellum with many rays on the margin. Meig. Curtis. *Brit. Ent.* vii. pl. cccxxxvii.

B. *vallata*. Antennæ dark brown; head and thorax shining black: abdomen reddish yellow, that of the male having two black spots at the base; legs rufous, the hinder half of the tibiæ and the tarsi brown: wings of the female scarcely inclining to brownish, the base and anterior margin yellowish, the stigma dark brown. Two and a half lines. *Stratiomys clavipes*, Fab.; *Beris nigritarsis*, Lat. This species is found pretty frequently throughout the greater part of Britain. We have observed it near Edinburgh, and in Roxburghshire; and it occurs in Essex, Kent and other parts of the south of England. We have ascertained the existence of *B. femoralis*, *B. clavipes*, (Linn.), and *B. chalybeata*, in the south of Scotland; and seven others inhabit the more southern portion of the island.

Genus Xylophagus, Meig. Antennæ with the second joint cup-shaped, the third elongate, eight-ringed; proboscis retracted: scutellum unarmed.

X. *ater*. Shining black: first joint of the palpi yellow, second black: thorax of the males entirely shining black, that of the female with three grey vittæ, the lateral ones somewhat abbreviated: anterior legs bright yellow, with the apex of the tarsi brown; hinder legs bright yellow, the apex of the thighs, of the tibiæ and tarsi, brown; halteres yellow. Male five, female six lines. Meig. *Zw.* ii. pl. xii. fig. 14. Lat.; *Empis subulata*, Panz. Apparently the only species of the genus found in Britain.

Genus Cœnomyia, Meig. Antennæ with the radical joint elongate, cylindrical, second cup-shaped, third conical, eight-ringed: scutellum bidentate.

C. *ferruginea*. Rust brown: thorax with two lines of changeable white, which disappear behind the middle: abdomen dark rust brown anteriorly, paler behind; the second segment with a rather large white spot on each side behind, the two following with a similar spot, but united by a narrow white line; belly rust yellow, the hinder margins, with the exception of the first, whitish; legs ferruginous: halteres bright yellow: wings brownish yellow, with ferruginous nerves. Six to seven lines. *Tabanus bidentatus*, Fab. Gmel. Lat.; *Sicus ferrugineus*, Fallen. Not unfrequent in Germany and other continental countries in the months of June and July. It has not hitherto been observed in Britain.

---

[1] For example, *Tipula Hortulana* of Linn. is the female of *B. Marci* described above.

[2] *Memoires*, t. v. p. 55, et pl. vii.

FAMILY III.—TABANII.

Antennæ projecting, approximating at the base, three-jointed; third joint from four to eight-ringed, or six-jointed: proboscis and palpi standing out: abdomen consisting of seven segments: halteres half covered: wings divaricating: onychii three.

a. Antennæ three-jointed.

Genus Pangonia, Fab. Antennæ with the basal joint cylindric, second cup-shaped, third elongate, subulate, eight-ringed: ocelli three: proboscis elongate, exserted: wings spreading.

P. *ferruginea.* Antennæ black, the second joint and base of the third yellow; proboscis black, the length of the thorax; the latter thickly covered with brownish-yellow pubescence: abdomen with similar pubescence, and marked with black spots on the back, the segments margined behind with whitish: belly rust-brown: wing-scales, halteres, and legs bright brown; thighs black: wings brownish. Eight lines. Lat. *Gen. Crust.* iv. 282. Inhabits Portugal. The genus contains six European species, none of which appear to occur in Britain.

Genus Silvius, Meig. Antennæ with the radical joint cylindrical, second cup-shaped, third subulate, five-ringed: ocelli three: palpi standing out, two-jointed, pilose, the second joint cylindrical in the male, conical in the female.

S. *Vituli.* Antennæ ochre-yellow, the apex black; hypostoma bright yellow; forehead of a similar colour, with a shining black callosity anteriorly in the female; palpi yellow, the apex black in the male: thorax yellow with a brown play of colour, pubescent: abdomen pubescent, yellow: wing-scales and halteres yellow, the knob of the latter whitish: wings with microscopic hairs, somewhat greyish, with the anterior margin yellow; legs yellow, with brown tarsi. Five to six lines. *Tabanus Vituli*, Fab.; *Tabanus Italicus*, Fab. This insect occurs on the continent, but we have no knowledge of its precise localities.

Genus Tabanus, Linn. (Plate CCXXXVIII. figs. 5 and 5 *a*). Antennæ with the basal joint cylindric, second cup-shaped, third compressed, the lowest ring very large and crescent-shaped at the base: ocelli wanting: palpi exserted, capitate in the male, subulate in the female: wings spreading.

T. *bovinus.* Antennæ black, reddish brown at the base: hypostoma, palpi, and forehead bright greyish yellow; the latter in the female with a black line, which terminates beneath in a shining black roundish callosity; eyes green during life: thorax dark brown, with yellowish hair, sometimes inclining to slate-colour, and having dark lines on the back: abdomen dark brown, with a rather wide reddish-yellow cross band on the hinder edge of the segments, and a row of bright yellow triangular spots down the middle: belly yellowish grey, darker behind the incisures, with rather large nearly triangular spots of black, and near these an oblique black line: thighs and tarsi dark brown; tibiæ bright yellow, the apex brownish: wing-scales and halteres brown, the apex of the latter pale; wings brownish, the anterior margin inclining to yellow. One inch. Linn.; Degeer, vi. 88. i. pl. xii. fig. 6–14. Common on the continent. It is not quite so plentiful in Britain, especially in Scotland, where we have seen it only on a few occasions in the northern and middle counties. We have taken it by the banks of Loch Katrine, and in Sutherland. Eighteen kinds of Tabani inhabit Britain, and upwards of twice that number are known as European. Besides *T. bovinus*, we are not acquainted with any other Scotch species except *T. tropicus* and *T. autumnalis*.

Latreille, Lepelletier and Serville, Meigen, Wiedemann, Macquart, and the late Palisot de Beauvis, have cleared away many of the difficulties which encumbered the systematic study of this and the allied genera; but their natural history, properly so called, has scarcely received any accession since the days of Degeer. It is to that great observer that we owe our knowledge of the manners and metamorphoses of the species above described, the only one in fact of which we have any detailed account. *T. maroccanus* is extremely troublesome to camels in the north of Africa. M. Defontaines has frequently observed their bodies entirely covered by these insects. The species occurs also in Portugal.

Genus Chrysops, Meig. (Plate CCXXXVIII. figs. 6 and 6 *a*). Named from χρυσος, *gold*, and ὄψ, *the eye*, which is usually very brilliant during life. Antennæ cylindrical, three-jointed, two basal joints equal, third longer, five-ringed: palpi exserted, two-jointed, pilose, the second joint conic: ocelli three: wings spreading.

C. *cœcutiens.* Male. Black; the eyes with two dark purple bands; the uppermost interrupted; hypostoma yellow, with large dark spots which nearly conceal the ground colour: forehead black: thorax with reddish pubescence on the sides and beneath: abdomen black, with a rufous spot on each side of the second segment; under side black brown, the two basal segments yellow, having a brown line in the middle: antennæ, palpi, legs, and halteres black: wings almost entirely brown; in the middle there is a small light-coloured spot; at the hinder margin, before the apex, a nearly uncoloured triangle, and not far from the base a pale mark.

The thorax of the female is lined with cinereous; the first segment of the abdomen has two yellow spots, the second is yellow, with two dark lines in the centre, enclosing a triangular mark of yellow behind: wings whitish; the base, anterior margin, a broad band rather behind the middle, and an apical spot, brown. Four lines. *Tabanus cœcutiens*, Linn.

Frequent in most countries of Europe. In Scotland it is rather scarce, but has been taken occasionally in Dumfriesshire, Roxburghshire, and elsewhere.

Genus Hæmatopota, Meig.; named from *αἷμα*, *blood*, and *ϖοτης*, *drinker*. Antennæ three-jointed, the second joint cup-shaped, third subulate, four-ringed: palpi exserted, two-jointed, second joint conic: ocelli wanting: wings parallel, deflexed. Meig. ii. 76. pl. xiv. f. 8–16.

H. *pluvialis.* Eyes greenish, with waved purple-brown bands: palpi and hypostoma light grey; antennæ scarcely longer than the head; first joint thick, oblong, shining-black, pubescent; thorax blackish, with whitish lines, the two next the middle having a white spot in the centre; sides of the breast light grey, somewhat pubescent: scutellum blackish, sometimes cinereous over the middle: abdomen blackish brown, with whitish incisures and a cinereous line down the back; on the third and following segments on each side of this line there is a round cinereous spot; in the males the three first segments are somewhat testaceous on the sides: belly brownish grey: thighs cinereous: anterior tibiæ yellow at the base, the apex, together with the tarsi, black brown; posterior tibiæ yellow, with three brown rings, one in the middle and another at each end; the tarsi black brown, with the first joint yellowish: halteres yellowish, having a brown spot on the knob: wings brownish-cinereous, with numerous waved lines of white, and a dark-brown marginal streak. Four to four and a half lines. Meig. ii. 78, pl. xiv. f. 16. *Tabanus pluvialis*, Linn. Very plentiful throughout Britain. This insect is known in Scotland by the name of *Cleg*, and is very troublesome during the heat of summer both to man and beast, particularly horses.

b. Antennæ six-jointed.

Genus Hexatoma, Meig.; named from ἓξ, *six*, and τόμος, *section*, in allusion to the number of joints in the antennæ. Antennæ six-jointed; the first and third joints elongate: palpi exserted, two-jointed; second joint capitate (in the male) or conical (in the female): ocelli wanting: wings parallel, deflexed. Meig. ii. 83, pl. xiv. f. 17–24. *Heptatoma*, Lat. *Gen. Crust.* iv. 284.

H. *bimaculata*. Hypostoma of the males shining-black, with yellowish hair; that of the female light grey above and yellow beneath; thorax blackish, with rufous pubescence: abdomen of the males black, the pubescence of the two basal segments brownish yellow; on the belly these segments are bluish white at the sides and blackish in the middle; the following black, with three pair of bluish-white transverse streaks: abdomen of the female black, the base with brownish-yellow pubescence, and the second segment with bluish-white lateral spots: feet black brown: wings vitreous. Six lines. *Tabanus pellucens*, Fab. A rare species, which has not yet been detected in Britain.

FAMILY IV.—LEPTIDES.

Antennæ porrect, approximating at the base, three-jointed; third joint without rings: proboscis and palpi exserted: ocelli three: abdomen consisting of seven segments: halteres uncovered: onychii three.

Genus Leptis, Fab. Antennæ with the first joint cylindric, second cup-shaped, third conic with an apical seta: palpi pilose, the second joint elongate: ocelli three, vertical: wings spreading.

L. *aurata*. Male. Hypostoma blackish grey; antennæ dark brown; thorax and abdomen thickly covered with shining golden hairs: halteres, thighs, and tarsi dark brown; tibiæ testaceous: wings pale brown, with the stigma reddish brown.

Female. Hypostoma and forehead dark grey, the latter broad: thorax and abdomen thickly clothed with light-yellow hairs; sides of the breast black; wings nearly hyaline, scarcely tinged with brown, the stigma reddish brown: halteres and legs as in the male. Three to four lines. *Rhagio atratus*, Fab. Lat.; *Rh. tomentosus*, Fab. In marshy meadows in May, common. This genus, as constituted by Meigen, contains twenty-two species; but more recent writers have separated it into two genera, corresponding to his sectional divisions. Nearly all of these inhabit Britain, and some are very abundant, particularly *L. scolopacea* and *L. tringaria*.

Genus Atherix, Meig. (Plate CCXXXVIII. figs. 7 and 7 *a*.) Antennæ with the terminal joint ovate, having a naked dorsal seta at the base: palpi standing out, pilose, incurved: ocelli three, vertical: wings spreading.

A. *Ibis*. Hypostoma and forehead bright yellow; the latter in the female yellowish with a brown vitta; thorax pubescent, yellowish brown, with broad lines of dark brown along the back; scutellum brown: abdomen of the males conical; the first segment dark brown, the following ferruginous with the hinder margin bright yellow, and marked with three black spots, one on the back and another on each side; on the last segments these spots run together; belly yellow: abdomen of the females ash-grey, the segments with a black band anteriorly, the hinder margin white; belly ash-grey: legs ferruginous, the tarsi brown at the apex: halteres yellow, the knob brown: wings hyaline, with irregular cross bands of reddish brown, which are paler in the female. Male four, female five lines. Curtis, *Brit. Ent.* i. 26; *Rhagio Ibis*, Fab.; ♀ *Atherix maculatus*, Lat.; *Anthrax Titanus*, Fab. Mr Curtis states that there are at present but two species of this genus recorded as natives of Britain, although twelve are enumerated as European. The species described appears to be everywhere rare. The male and female were placed by Fabricius in different genera.

Genus Clinocera, Meig. Antennæ remote, the lower joints spherical, the third conical with an incurved terminal seta: ocelli three, placed on the forehead: wings incumbent, parallel.

C. *nigra*. Head black; body dull black; thorax with three darker lines; legs long, slender, and black: halteres black, uncovered: wings hyaline. Two lines. Found in Germany and elsewhere.

FAMILY V.—XYLOTOMÆ.

Antennæ projecting, approximating at the base, three-jointed, the third joint without rings: proboscis concealed: ocelli three: abdomen seven-ringed, conical: halteres uncovered: wings spreading: onychii two.

Genus Thereva, Lat. Antennæ with the radical joint cylindrical, second cup-shaped, third conical: proboscis retracted: ocelli three: wings spreading.

T. *fulva*. Ferruginous, with pubescence of a similar colour, intermixed with black hairs on the thorax; two first joints of the antennæ ferruginous, the third dark brown: on the forehead of the females is the usual shining black spot, and the hinder extremity of the abdomen is likewise black: thighs and tarsi brown; tibiæ ferruginous: halteres yellow: wings nearly hyaline, the anterior border yellowish. Four to five lines. This insect is of not unfrequent occurrence in the south of Scotland, where *T. anilis* and *T. plebeia* are likewise found. The former is distinguished by its reddish thorax, and abdomen of a silvery-white or grey colour. It is generally seen sitting upon sand, but flies off suddenly if an attempt is made to seize it. Meigen mentions twenty species. Britain produces about one half of that number.

FAMILY VI.—MYDASII.

Antennæ projecting, five-jointed, the joints without rings, the terminal one club-shaped.

Genus Mydas, Lat. (Plate CCXXXVIII. figs. 8 *a* and 8 *b*.) Antennæ with the two lowest joints small, the following cylindrical, the terminal one clavate. Proboscis exserted.

M. *lusitanicus*. Entirely black, except the hinder edge of the abdominal segments, which are yellowish white: beard and mystax[1] white: the sides of the thorax and two first segments of the abdomen are beset with long white hairs, and the back of the abdomen and legs with short white pubescence: wings yellowish. Eight lines. Inhabits Germany, Portugal, &c. Another species, named

---

[1] This term is applied to a semicircle of bristles or hairs placed over the mouth.

M. filatus, is found in America. It is figured by Drury.[1] Brazil produces one above two inches long.

FAMILY VII.—BOMBYLIARII.

Antennæ projecting, three-jointed; third joint without rings: hypostoma beardless: forehead flat: (proboscis retracted or somewhat projecting) ocelli three: abdomen consisting of seven rings, cylindric or elliptical: wings spreading: halteres uncovered.

Genus Hirmoneura, Wied. Antennæ remote, the joints sub-globose, equal, the third with a terminal style: ocelli three, the anterior one remote: proboscis retracted and concealed.

H. *obscura.* Hypostoma ochre yellow; forehead cinereous with blackish hairs: thorax black, with yellowish hairs on the sides, those on the breast more inclining to grey: abdomen with the lateral edges yellow, the upper side with yellowish grey pubescence, the apex of the segments slate grey; belly yellowish, and covered with pubescence similar to that on the breast: wings brownish grey, especially at the anterior margin: halteres dark brown: legs ochre yellow, the tibiæ and tarsi a little darker: extremity of the abdomen with two short truncated styles. Seven and a half lines. Found in Dalmatia.

Genus Fallenia, Meig. Antennæ remote, the joints sub-globose, the last with an elongate terminal style: proboscis the length of the body, and bent beneath the breast.

F. *caucasica.* Head and thorax covered with whitish hair; eyes of a metallic hue: abdomen nearly orbicular, with blackish pubescence; the first segment wide, with grey pubescence, the following fringed with whitish grey upon the hinder edge; the anus ferruginous: wings yellowish: legs brownish grey, with rather indistinct grey hairs. Five to five and a half lines. *Volucella caucasica*, Wied. *Zool. Mag.* i. 2, 7. Found in Russia and elsewhere, but appears to be scarce. There is only one other species, *F. fasciata*, Fab. a native of Italy.

Genus Stygia, Meig.[2] Antennæ approximating, the first joint dilated at the apex, and obliquely truncate, second cup-shaped, third conical: head sub-globose; eyes kidney-shaped: proboscis retracted.

S. *Belzebub.* Male. Hypostoma and forehead black, the last having a tendency to pass into grey over the antennæ: thorax wholly shining black, with pubescence of the same colour: abdomen shining black, the hinder margin of the segments (with the exception of the first) narrowly edged with yellow; the pubescence on the sides of the first segment whitish, and on the following black: belly entirely black: wing-scales black, fringed with white hair: stalk of the halteres brown, the knob pale yellow: legs black. Five to six lines. *Anthrax Belzebub*, Fab. This fly is found in France, Italy, Hungary, England, and in most other parts of Europe.

Genus Anthrax, Scop. (Plate CCXXXVIII. figs. 9 and 9 *a.*) Antennæ distant, the first joint cylindrical, second cup-shaped, third sub-globose, with an elongate or conical style; eyes kidney-shaped: proboscis retracted or very slightly produced.

A. *flava.* Hypostoma with bright yellow pubescence; forehead black, with short rufous hairs, which are mingled with black ones: antennæ black: thorax and abdomen covered throughout with long reddish shining hairs, the anus having pale yellow hairs, and three black tufts: stalk of the halteres brown, the knob yellow: wings hyaline, with a yellowish-brown streak along the anterior edge, and the base with a pectinated mark of black: wing-scales brownish yellow: legs black; thighs and tibiæ sprinkled with yellow. Seven lines. *Anthrax hottentotta*, Fab.; *Musca hottentotta*, Don. xiv. 69, pl. ccccxciv. Inhabits England, France, and Holland, occurring not unfrequently. This genus, as constituted by Meigen, contains about sixty species, a small proportion of which has yet been detected in Britain. We know little of their history or transformations.

Genus Mulio, Lat. Antennæ distant, the first joint short and cylindrical, second cup-shaped, third conical, acute; eyes elliptical: proboscis standing out, horizontal.

M. *infuscatus.* Hypostoma with ash-grey hairs; the forehead with dark-brown hairs; proboscis as long as the head: thorax dark brown, ash-grey on the sides: abdomen flat and arched, with ferruginous hairs, the incisures beset with numerous black bristles; halteres brown, the knob almost entirely white; wings light brown, the apex hyaline: legs yellow and glistening; the tarsi brown. Three and a half lines. Found in Provence by M. Baumhauer.

Genus Bombylius, Linn. (Plate CCXXXVIII. figs. 10 and 10 *a.*) Antennæ approximating, the first joint cylindrical, second cup-shaped, third elongate and compressed; proboscis standing out, longer than the head: body woolly.

B. *minor.* Beard whitish; mystax reddish: the sides covered with black hairs: forehead of the females with reddish hair: antennæ and proboscis black: ground colour of the body deep black, the whole surface covered with rufous hairs: halteres dark brown; wings somewhat greyish, the base and anterior margin more or less rufescent. Four lines; the proboscis from two and a half to three lines. Fab. Linn. Found in several parts of England: we have often observed it in considerable abundance on the sides of Arthur's Seat, and in the fields to the south of Duddingston. About six other species occur in Britain; and although the appearance of these is very familiar, naturalists in truth know little or nothing of their transformations. Latreille supposes that their larvæ are parasitical. Nearly fifty European species are described by systematic authors.

Genus Phthiria, Lat. Antennæ approximating, the two lower joints short and equal, the third elongate, spindle-shaped, compressed: proboscis standing out, horizontal, elongate: palpi clavate.

P. *minuta.* Male. Hypostoma and forehead black, and covered with black hairs: body wholly deep black, with soft and rather long black hairs: wings smoke-brown, the stigma brown: halteres and legs black.

Female. Hypostoma white; the forehead blackish, the margin of the eyes white: body black, with traces of white hairs; scutellum yellow, having a dark-brown streak along the sides: under side of the breast whitish; halteres brown above, white beneath: wings brown, but considerably paler than those of the male: legs black. One and a half line. Lat.; *Volucella minuta*, Fab. Occurs, along with five other species, on the continent of Europe.

Genus Geron, Hoff. Antennæ approximating, the first joint elongate, cylindrical, second cup-shaped, third

---

[1] *Illustrations*, vol. i. tab. 44, fig. 1.

[2] The name of this genus is defective, in as far as it has been already applied to a lepidopterous genus. Meigen has since altered it to *Lomatia*, which is scarcely more fortunate, as it also has been previously applied by Mr Brown to a genus in botany of the family of Proteaceæ. Latreille has altered the original designation to *Stygides.*

Diptera Proboscideæ.

cylindric-subulate: proboscis standing out, horizontal, elongate.

G. *gibbosus*. Hypostoma and forehead white; antennæ black; thorax whitish grey, with two wide lines of brownish black down the back: scutellum and abdomen black: halteres white; wings hyaline, inclining to pale yellow at the anterior border: legs dark grey. Two and a half lines. Has been found in Bucharia by M. Baumhauer in the month of July.

Genus Usia, Lat. Antennæ approximating, the first joint sub-cylindrical, very short; second cup-shaped; third spindle-shaped, elongate, obtuse: proboscis standing out, elongate, horizontal, acute.

U. *ænea*. Dark brassy: forehead white anteriorly, greyish behind, with a shining black vitta; hinder part of the head cinereous, and marked with a shining black streak in the centre: wing-scales and halteres white: abdomen finely pubescent, wide, flat, and arched; the belly whitish yellow, marked with black cross bands which are abbreviated at the sides: wings hyaline, with a yellow base and a large black spot near the middle of the anterior margin: legs black, with a metallic lustre. Two and a half to three lines. Lat. *Gen. Crust.* iv. 315. Found near Bourdeaux and elsewhere.

Genus Ploas, Fab. Antennæ approximating, the first joint very thick and conical, second cup-shaped, third spindle-shaped, and furnished with a jointed style at the apex; proboscis standing out, horizontal, the length of the head.

P. *grisea*. Colour varying from black to slate-grey: thorax marked with four grey lines, the two in the middle united anteriorly: halteres white: abdomen griseous: wings brownish at the base and anterior margin. Three and a half lines. *Bombylius griseus*, Fab. Inhabits Germany, Spain, &c.

Genus Cyllenia, Lat. Antennæ approximating, the first joint cylindrical, second very short, cup-shaped, third conical with a simple style at its apex: eyes oval: proboscis somewhat standing out, horizontal.

C. *maculata*. Antennæ with the radical joint brownish grey, second white, the third black: forehead black, the margin of the eyes white: thorax black, with yellowish-grey pubescence, mixed with long black hairs: abdomen with the first segment brown, the following pale yellow anteriorly, brown behind, with reddish-yellow hair and long black ones intermixed; on each segment are two longitudinal lines of black, diverging behind, and a black spot: halteres pale yellow above, brown beneath: legs black, covered with matted hair of a ferruginous colour: wings pale brown at the anterior edge, and sprinkled over the surface with dark-brown spots. In the male the hinder thighs are much thicker than in the female. Three to four lines. Lat. *Gen. Crust.* iv. 312. The species described is the only one belonging to the genus. It appears to be more frequent in France than in any other European country.

Genus Toxophora, Meig. Antennæ longer than the head, approximating, the two lower joints cylindrical, the third conical; proboscis standing out, arched, one half longer than the head; the palpi slender, cylindrical, bent and acute.

T. *maculata*. Hypostoma white, the hinder part of the head of a similar colour; thorax black, covered with a sulphur-coloured down on the sides and back: abdomen clothed in a similar manner, and having two rows of naked black spots down the back: legs black, with white down, the tibiæ somewhat bristly: halteres white, uncovered: wings hyaline, the anterior margin and the base yellowish. Four lines. This rare fly has been found in the south of France and in Russia. It appears to have been formerly described by Villers under the title of *Asilus fasciculatus*.[1] It was brought from Syria by Labillardière, and is justly admired as a beautiful and interesting species.

The genus is widely distributed, and probably requires subdivision. We have received species from Brazil. Meigen Le Conte has taken it in the United States. Wiedemann describes a species from Java; and *Bombylius cupreus* of Fab. which is now regarded as a Toxophora, is native to Cayenne.

FAMILY VIII.—ASILICI.

Antennæ projecting, approximating at the base, turned upwards, three-jointed; the third joint without rings: hypostoma with a mystax: forehead depressed: proboscis projecting horizontally, short: abdomen consisting of seven segments: halteres uncovered: wings parallel, incumbent.

a. Tarsi with two onychii.

Genus Dioctria, Meig. Antennæ inserted into a frontal tubercle; first joint cylindric, second shorter, somewhat cup-shaped; third elongate, compressed, the apex with a blunt two-jointed style: proboscis exserted, short, nearly horizontal: hinder legs straight, ciliated beneath: wings incumbent.

D. *rufipes*. Shining black: hypostoma bright brass-yellow, shining: on the thorax are two changeable white lines, which, however, are scarcely observable in the males; the sides of the thorax with silvery streaks: halteres yellow: legs rufous, the hinder pair dark brown: wings hyaline. Six to seven lines. *Asilus rufipes*, Degeer. Not a rare insect throughout England: in Scotland it is far from scarce, and *D. lateralis* frequently occurs in company with it. Meigen describes twenty-eight species, eleven of which have been detected in Britain.

Genus Dasypogon, Meig. (Plate CCXXXVIII. figs. 11 and 11 *a*). Named from δασυς, *hairy*, and πωγων, *a beard*. Antennæ with the two lower joints sub-cylindric, equal, third elongate, compressed, somewhat spindle-shaped, the apex with a short two-jointed style: proboscis horizontal, the length of the head: tibiæ straight.

D. *ruficornis*. Thickly pubescent: antennæ ferruginous, black at the base; mystax ferruginous, the forehead dark brown: thorax shining brownish black, with yellowish-grey spots, and having white hairs anteriorly: scutellum black: abdomen deep black, shining, the hinder half of the second segment and the whole of the third and fourth dull ferruginous, the fifth in the female with a ferruginous margin behind: belly shining black; legs very hairy, dark brown, the tarsi reddish brown: halteres brown, with a yellow knob. Seven to eight lines. *Asilus ruficornis*, Fab.; Meig. *Zw.* ii. pl. xx. fig. 11. This insect occurs in France. The genus contains forty-four European species, only two of which, viz. *D. punctatus* and *D. brevirostris* (Curtis, *B. E.* fol. 153), have been noticed in Britain.

Genus Laphria, Fab. Antennæ with the radical joint cylindric, second cup-shaped, third clavate, obtuse: proboscis standing out, horizontal: tibiæ arched.

L. *gibbosa*. Beard pale-yellow, with a brownish play of colour: thorax black, with reddish-brown hairs: three first segments of the abdomen shining black, the three following clothed with whitish-yellow down; the seventh black, retracted: belly and legs black, the latter with brown pubescence: nervures of the wings margined with yellowish brown: halteres black. Ten lines. *Laphria gibbosa*, Fab.; *Asilus gibbosus*, Fab. Found in various parts of Europe. *L. nigra* (Curtis, *B. E.* fol. 97) is the only species of the genus, which contains thirty-two different kinds, satisfactorily ascertained to inhabit Britain. It has been found in Darent Wood, Kent, in the vicinity of London, and at Coombe Wood.

---

[1] *Entom. Lin.* iii. pl. 10, fig. 31.

GENUS ASILUS, Linn. Antennæ with the basal joint cylindric, second cup-shaped, third subulate, compressed, having a setiform apical style: proboscis exserted, horizontal: tibiæ straight, spinulose.

A. *crabroniformis*. Head yellow: two basal joints of the antennæ rufous, third brown: thorax rufous, with two brown dorsal lines, which are usually obsolete, behind: scutellum brown: three basal segments of the abdomen deep black, the second incisure with a white spot on each side; the remaining segments rufous, with a fine glistening lustre; that of the female bent downwards and terminating in a black style: legs rufous, with brownish thighs: halteres brownish yellow: wings pale yellow, the hinder margin spotted with fuscous. One inch nearly: the male rather less. Meig. ii. 309; Linn. *Fauna Suec.* 1908. Occurs throughout Europe, and in some countries of Asia. The genus is extensive (containing nearly sixty European species), and a considerable number inhabit Britain,—some of them being rather common. *A. opacus* abounds in several parts of Scotland. All the species are carnivorous, and prey upon other Diptera. They even attack hymenopterous insects. Their flight is rapid, and frequently attended by a buzzing sound. They occur in woods and various other places, chiefly in autumn, or the end of summer. Their structure and metamorphoses have been illustrated by Frisch,[1] Degeer,[2] and Marcel de Serres.[3] The larvæ live under ground.

b. Tarsi without onychii.

GENUS LEPTOGASTER, Meig. Antennæ with the two lowest joints short, cylindrical, equal; third conical, with the apex pilose: proboscis horizontal, short.

L. *Pallasii*. Naked: thorax slate-grey, black when seen in certain directions; sides of the breast whitish: first segment of the abdomen very small; the last nearly club-shaped, all of them margined with light grey: legs pale yellow, with a ring on the thighs, the apex of the tibiæ and the tarsi brown: hinder legs much longer than the anterior ones, club-shaped, with a ring near the apex: halteres pale: wings with the lower half brown, the remainder hyaline. Four and a half lines. Found in the south of Russia. It is rare.

FAMILY IX.—HYBOTINÆ.

Antennæ projecting, approximating at the base, three-jointed: the first two joints united so as to form one, the third without rings: hypostoma beardless, flat: forehead flat: proboscis projecting horizontally, short: thorax much arched: abdomen slender, consisting of seven rings: halteres uncovered: wings parallel, incumbent.

GENUS HYBOS, Fab. Antennæ with the two lowest joints united, cylindrical; the third conical, with a pubescent seta at the apex: hinder thighs thickened.

H. *funebris*. Black, with a whitish hypostoma, and pale yellow halteres: thorax with a white play of colour behind: wings with a dark-brown stigma. Two lines. *Asilus culiciformis*, Fab. Common everywhere in hedges and among grass. Four other species in addition to the above are indigenous to Britain.

GENUS OCYDROMIA, Hoff. (Plate CCXXXVIII. figs. 12 and 12 *a.*) Antennæ with two lowest joints united, cylindrical; third lenticular, bearing a seta at the apex: proboscis sub-exserted, horizontal: all the legs simple.

O. *flavipes*. Antennæ dark brown; palpi yellow: thorax and abdomen entirely black: halteres yellow: legs yellow, all the tarsi brown; the hinder coxæ, the apex of the hinder thighs, and the tibiæ, are likewise brown: wings somewhat brownish. Three lines. Found in England and on the continent.

GENUS OEDALEA. Antennæ with the first joint cylindrical, short; second cup-shaped, third elongate, conic, compressed; proboscis short and horizontal: hinder thighs thickened and spinose beneath.

O. *minuta*. Body black, finely pubescent, shining: halteres brown: legs pale reddish yellow; in the anterior pair the tibiæ and tarsi are brown, and in the hinder pair the tarsi only are of that colour: wings brownish, with a long brown stigma. One and a half line. *Empis minuta*, Fallen. Found in Britain, France, &c.

FAMILY X.—EMPIDIÆ.

Antennæ porrect, approximating at the base, three-jointed, the third joint without rings, and having a style or a seta at the apex: hypostoma beardless: ocelli three: proboscis exserted, very perpendicular, with incurved palpi: abdomen consisting of seven segments: wings parallel, incumbent: onychii two. Meig. iii. 1.

GENUS HILARA, Meig. (Plate CCXXXVIII. figs. 13 and 13 *a.*) Antennæ with the basal joint cylindric; second cup-shaped, third subulate, compressed, the apex with a two-jointed style: proboscis thick, shorter than the head: wings incumbent, parallel, with an oblique transverse nervure at the apex. Meig. *Zw.* iii. pl. xxii. f. 1–5.

H. *cilipes*. Dusky black, antennæ reddish brown: wings fuscous; halteres whitish; the anterior metatarsus of the male dilated in an elliptical form, and fringed on the external margin with long hairs. Two lines. Meig. *Zw.* iii. 3, pl. xxii. fig. 3; Curtis, *B. E.* 130. Found near London. Upwards of twenty species belong to the genus, and nearly all of them inhabit Britain.

GENUS BRACHYSTOMA, Meig. Antennæ with the first joint cylindric, second cup-shaped, third conic, with a very long terminal seta: proboscis the length of the head: wings incumbent, parallel.

B. *vesiculosa*. Hypostoma greyish white; forehead narrow, black: antennæ as long as the head, black; the two first joints of equal length, the third with a long apical seta bent downwards: proboscis perpendicular, nearly as long as the head: thorax shining black, cinereous on the sides: scutellum very small: abdomen cylindrical, black; the seventh segment very much inflated, pellucid, waxen yellow: halteres white: wings hyaline, with a scarcely perceptible pale marginal streak: coxæ cinereous, short; thighs ferruginous; tibiæ at the base, and the tarsi, brown. Two and a half lines. *Baccha vesiculosa*, Fab. Inhabits Britain and the continent of Europe.

GENUS GLOMA, Meig. Antennæ with the first joint cylindric, very slender, second cup-shaped; third globose, with an apical seta: proboscis the length of the head, thick.

G. *fuscipennis*. Antennæ black; thorax of the same colour, pubescent: abdomen pubescent, black brown, with yellowish incisures: halteres brown: wings brown, with a dark marginal streak; legs pubescent, brown; all the thighs and the hinder tibiæ with a groove on both sides; the hinder legs as long as the anterior ones. Two lines. Meig. *Zw.* iii. pl. xxii. fig. 11. Inhabits England, but is very scarce.

---

[1] In his work on the *Insects of Germany*.

[2] *Mémoires*, t. vi.

[3] *Annales du Mus. d'Hist. Nat.* t. iv. p. 361.

Genus Empis, Linn. Antennæ with the basal joint cylindric, second cup-shaped, third conic, compressed, the apex with a two-jointed style: proboscis perpendicular or bent inwards, longer than the head, slender: wings with a transverse nervure at the apex, incumbent, parallel. Meig. *Zw.* iii. 15, pl. xxii. fig. 13–20; Curtis, *B. E.* pl. xviii.

E. *tessellata.* Palpi, antennæ, and proboscis black, the latter as long as the head and thorax: hypostoma and forehead cinereous; thorax of the same colour, bristly, with three dorsal lines black, the central one narrowest: abdomen hairy, cinereous, with a line down the back, and the hinder margin of the segments blackish; when seen in another direction both colours change, the black becoming grey and the grey black: halteres yellowish: wings brown, ferruginous at the base: legs black, the tibiæ testaceous, shining. Five to six lines. Meig. Fab. *E. livida*, Fab. var. Common on flowers, during summer, in England and Scotland, and most parts of Europe: it has been likewise taken by Pallas in Tauria. Twenty-eight species of Empis occur in Britain, and nearly double that number are known to entomologists. Their early states have not been well determined. In the perfect state they prey upon other flies.

Genus Rhamphomyia, Hoff. Antennæ with the radical joint cylindric, second cup-shaped, third conic, compressed, the apex with a two-jointed style: proboscis perpendicular or bent inwards, slender: wings incumbent, parallel, the transverse nervure at the apex wanting. Meig. *Zw.* iii. 42.

R. *longipes.* Deep shining black, as well as the legs: proboscis twice the length of the head, slender: halteres dark brown: wings hyaline, with a scarcely perceptible stigma: in the males the hinder legs are stout, elongate, and pubescent; the hinder tibiæ somewhat clavate, and the first joint of the tarsi distinctly thickened: in the female the anterior legs are simple. Found in summer, but is rare.

FAMILY XI.—TACHYDROMIÆ.

Antennæ porrect, approximating at the base, two-jointed, with an apical seta: ocelli three: proboscis short, perpendicular: palpi incumbent on the proboscis: abdomen consisting of seven segments: onychii two.

Genus Hemerodromia, Hoff. (Plate CCXXXVIII. figs. 14 and 14 *a*). Antennæ with the first joint cylindric, second ovate, the apex supporting a seta: proboscis short and perpendicular, with incumbent palpi, which are subulate or cylindric: anterior coxæ elongate: wings incumbent, parallel. Meig. *Zw.* iii. 61, pl. xxiii. fig. 5–15.

H. *monostigma.* Yellowish white: forehead cinereous: on the thorax are two cinereous vittæ, which anteriorly are drawn into two black lines: along the back of the abdomen runs a black line, which is notched or sinuated on both sides: the fifth joint of the tarsi is black; wings hyaline, with a marginal spot of black. Two lines. Meig. *Zw.* iii. pl. xxiii. fig. 6. Found in the south of England and elsewhere.

Genus Tachydromia, Meig. *Sicus*, Lat. Antennæ with the first joint cylindric, second ovate or oblong, with a terminal seta: the anterior or intermediate thighs thickened: wings incumbent. Meig. *Zw.* iii. pl. xxiii. fig. 16–24.

T. *fasciata.* Palpi yellow, proboscis black; hypostoma white; forehead cinereous; antennæ black, with the basal joint yellow: thorax cinereous: abdomen shining black, with a broad cinereous ring, interrupted in the middle, at the base of each segment: halteres bright yellow: legs rufous, the tarsi black at the apex: wings yellowish. Two lines. Meig. *Zw.* iii. pl. xxiii. fig. 22. Has been taken by Dr Leach in England, where thirty-three other species occur. Few of these have been ascertained to inhabit Scotland. *T. minuta*, however, has lately been found near Edinburgh. There are about sixty species in Europe.

Genus Drapetis, Meig. Antennæ with the first joint cylindric, second lenticular, with a seta at the apex: proboscis scarcely exserted, very short, perpendicular, covered by the palpi: wings incumbent, parallel. Meig. *Zw.* iii. pl. xxiii. fig. 25–28.

D. *exilis.* Head black, nearly round; antennæ black: thorax shining black, without a transverse suture above: abdomen of the males entirely shining black, rather long, nearly cylindric; that of the female more oval, pointed, reddish yellow above, with a black transverse band at the hinder margin of the segments, entirely ferruginous yellow beneath: thighs somewhat thickened, black; tibiæ brown, unarmed; tarsi yellow: halteres black: wings hyaline. Male half a line, female three fourths of a line. Said to be common in hedges during the months of August and September, in various parts of the continent.

FAMILY XII.—INFLATÆ.

Antennæ very minute, two-jointed: head almost entirely occupied by the eyes: ocelli three: abdomen very thick, consisting of five segments: onychii three.

Genus Cyrtus, Meig. *Acrocera*, Fab. Antennæ nearly vertical, the first joint cylindric, second ovate with a terminal seta: proboscis exserted, horizontal, longer than the head. Meig. *Zw.* iii. pl. xxiv. fig. 1–6.

C. *gibbus.* Proboscis and palpi yellow: thorax nearly globose, arched, pubescent, yellow, with a black dorsal line anteriorly, which is widened in the middle into a large spot: scutellum semicircular, black, with a triangular spot of yellow at the hinder margin: abdomen very thick, inflated, globular, flat beneath, of a yellow colour, with four black cross bands produced in the middle into a point: wing-scales large and cinereous; the halteres small, and yellow: wings lanceolate, hyaline, yellowish at the anterior margin: legs ferruginous. Four to five lines. A rare insect, found occasionally in the south of Europe and in the north of Africa. The species in general frequent flowers.

Genus Acrocera, Meig. Antennæ vertical, the second joint spindle-shaped, with a terminal seta: proboscis concealed. Meig. *Zw.* iii. pl. xxiv. fig. 7–10.

A. *sanguinea.* Thorax black, naked, with a white spot on the shoulder, and a whitish line before the wing-scales: abdomen blood-red, with four dorsal spots, the three anterior ones triangular: legs black: wing-scale blackish brown: wings brownish, the marginal nervures dark. Three and a half lines. Meig. *Zw.* iii. pl. xxiv. fig. 10. The species are few in number, and frequent moist places. The one just described is found on the continent. Two others, *A. globulus* and *A. albipes*, inhabit England.

Genus Henops, Illig. (Plate CCXXXVIII. figs. 15 and 15 *a.*) Antennæ porrect, inserted into the upper margin of the mouth, the basal joint patelliform, second ovate, with a terminal style thickened at the apex: proboscis concealed.

H. *marginatus.* Thorax black, with fine grey pubescence: abdomen black brown or pitch colour, the hinder margin of the segments white: legs entirely rufous: wing-scales and wings hyaline, the last with yellowish-brown

Diptera Proboscideæ.

marginal nervures: belly white, with dark-brown bands. Two to three lines. Meig. *Zw.* iii.; Curtis, *Brit. Ent.* pl. cx. This species has been frequently taken in the New Forest.

FAMILY XIII.—STRATIOMYDÆ.

Antennæ porrect, approaching at the base, three-jointed; third joint ringed: proboscis along with the head projecting: ocelli three: abdomen with five segments: onychii three.

Genus Pachygaster, Meig.; named from παχυς, *thick*, and γαστερ, *the belly*. Antennæ with the third joint globose, four-ringed, and having a terminal seta: scutellum unarmed. Meig. *Zw.* iii. pl. xxiv. fig. 16–23.

P. *ater.* Antennæ of the males brownish, of the females rufous: forehead of the males triangular, small, shining white, with a longitudinal furrow; the crown with three ocelli: thorax rather elongate, black; scutellum unarmed: abdomen wider than the thorax, arched above, flat beneath, black, naked: legs pale yellow with black thighs: halteres with a yellowish stalk and a black-brown knob: wings lanceolate, microscopically pubescent, when in a state of repose lying parallel with the body; the basal half brown, the rest hyaline. Two lines. *Vappo ater*, Lat. Leach. Not a scarce insect on the continent, and in this country it has been found in Darent, Birch, and Coombe Woods, besides various other places. The larva is elongated, of a reddish grey, marked with three obscure longitudinal bands.[1] Another British species is represented in Curtis' *Brit. Ent.* fol. 42, and named after Dr Leach, by whom it was discovered in Devonshire. The most obvious mark of distinction is derived from the appearance of the wings, which are uniformly hyaline in *P. Leachii*, while the lower half is brown in *P. ater*.

Genus Sargus, Fab. (Plate CCXXXVIII. figs. 16 and 16 *a.*) Antennæ with the first joint sub-cylindric, second cup-shaped, third lenticular, three-ringed, having an apical seta: scutellum without spines. Meig. iii. 104; Lat. *Gen. Crust.* iv. 278.

S. *Réaumuri.* Male. Head black; forehead with two white spots over the antennæ, the latter black brown; eyes green, without purple bands: thorax shining brassy green above, with a longitudinal line of white on each side: abdomen bright copper colour, with yellowish white pubescence: halteres and feet rufescent, the tarsi brown at the apex: wings reddish brown, the stigma somewhat obscure. Six lines. Meig. iii. 109; Réaumur, *Ins.* iv. 22, pl. 5–8.

The female is considerably less than the male, and is strikingly distinguished by having the abdomen of a bright steel blue, with the two basal segments red, having a narrow steel-blue line on the back. This sex is figured by Mr Curtis, *B. E.* pl. cccv. This beautiful species has been taken occasionally in England, and has been observed oftener than once near Edinburgh. On one occasion Mr Duncan found both sexes abundant in an open wood on the banks of the Teviot. All the species hitherto described occur in Britain, excepting two. Several, particularly *S. infuscatus*, *S. politus* (*Musca polita*, Linn.), and *S. formosus*, are common throughout the south of Scotland, the two former frequenting woods and gardens, the latter marshy meadows. *S. flavipes* (Meig. pl. xxvi. f. 14), which appears to be one of the rarer species, has been captured among the Pentland Hills.

The insects of this genus delight in warm and sunny weather. During cloudy days they may be found upon the leaves of various plants, dull, inactive, or in a state of stupor. One of the larvæ has been described by Réaumur. Its form was oblong-oval, narrowed to a point in front; the head scaly, furnished with a couple of hooks; the body thinly beset with hairs. It was found in cow-dung. It became a chrysalis without changing its skin, and the perfect insect made its exit by knocking off the anterior lid of its hardened envelope. Macquart divides the genus into two sections.

Genus Nemotelus, Fab. Antennæ inserted into the apex of a conical hypostoma, the lower joints equal, third elongate, spindle-shaped, four-ringed, the apex with a two-jointed style: scutellum without spines. Meig. *Zw.* iii. pl. xxv. f. 16–20.

N. *uliginosus.* Male. Forehead black, with a whitish spot over the antennæ: thorax shining black, with fine cinereous pubescence, and a white vitta extending from the shoulder to the base of the wing: scutellum black: abdomen white, black at the base, and having a spot of the same colour before the apex: legs white; thighs black, with a white apex; hinder tibiæ black, white at the base and apex: halteres white: wings hyaline, the marginal nervures yellowish.

Female. Shining black: head with short whitish silken hair, and an interrupted cross band of the same colour over the antennæ: thorax with short whitish silky pubescence, the shoulders and a line on each side running to the base of the wings, white: abdomen surrounded with yellowish white, and marked with three rows of triangular spots, the side rows united to the yellowish margin: in other respects like the male. Three lines. Meig. *Zw.* iii. 114, pl. xxv. fig. 19, *female.* *Musca uliginosa*, Linn.; Don. xv. 31, pl. 519.

Found in meadows and marshy places, in Britain and on the continent of Europe.

Genus Clitellaria, Meig. Antennæ with the two lowest joints nearly equal, the third conic, five-ringed, with a two-jointed terminal style. Meig. *Zw.* iii. pl. xxv. f. 21–25.

C. *Ephippium.* Hypostoma and forehead black, the latter in the female with two whitish pubescent spots: antennæ black brown: thorax covered with a silky pile of a fiery red colour, the sides and breast black; before the base of the wing there is a black pubescent spine: scutellum black, with two pubescent spines rising from the hinder edge: abdomen black: halteres yellow: wings smoke colour, deepening at the anterior edge: legs black, the hinder tibiæ somewhat crooked. Five lines. Meig. *Zw.* iii. pl. xxv. f. 25. Inhabits Germany, France, Switzerland, and England.

Genus Oxycera, Meig. Antennæ with the two lowest joints equal; third spindle-shaped, four-ringed, with a two-jointed terminal style: scutellum armed with two spines.

O. *pulchella.* Male. Hypostoma black, with whitish-grey pubescence: eyes with a purple fascia: forehead with two silver-white pubescent spots: antennæ black: thorax black: from the shoulder extends a yellow vitta to the base of the wings, where it turns downwards somewhat pointedly; behind the base of the wing towards the scutellum there is a yellow triangle: scutellum and spines yellow, the latter with a blackish apex: abdomen black, each side of the third and fourth segment with a long spot of a fine yellow colour directed forwards, and a triangular one on the terminal segment: belly black, the second, third, and fourth segments yellowish in the middle: legs yellow: thighs black in the middle: the anterior tarsi with the four last, and the others with the three last joints, blackish brown: halteres yellow: wings hyaline, the nervures brown.

---

[1] Macquart, *Dipt. du Nord de la France*, p. 112.

Female. Hypostoma and forehead yellow, with a black vitta in the middle; crown black; hinder margin of the eyes yellow: on the first segment of the abdomen, beneath the scutellum, is a yellow spot: in other respects the same as the male. Three lines. Meig. *Zw.* pl. xxv. f. 29; *Musca hypoleon*, Don. v. 6, pl. cxlvi. f. 3. Found in summer on hedges and bushes near lakes and marshes.

Genus Stratiomys, Geoff. Antennæ with the second joint cup-shaped, third elongate, somewhat spindle-shaped, five-ringed: scutellum armed with two spines.

S. *Potamida.* Thorax fuscous; scutellum with a black band at the base, the spines entirely yellow: abdomen black, the second segment with a yellow triangular spot on both sides, and on the hinder margin of the third segment there is a narrow band of yellow, which is broad and interrupted in the males, but entire in the females; the following segments have a narrow band in both sexes, and the anal one is marked with a yellow triangle: the belly is dirty yellow marked with four bands of black, the first one interrupted. From six to seven lines. *Musca Chamæleon*, Harr. *Ex.* 44, pl. xi. fig. 1. Of occasional occurrence in Britain, and on the continent of Europe. *S. Chamæleon* is more frequently met with in this country, particularly in the more northern parts.

The manners of these insects have been studied by Geoffroy and Réaumur. The larvæ have a long flattened body, covered by a coriaceous or rather solid skin, divided into segments, of which the last three, more slender and elongated than the others, form a tail terminated by a radiated expansion of barbed or plumy hairs. The head is scaly, small, oblong, and provided with a great many appendages and hooks, with which they agitate the water in which they dwell. They respire by an opening in the caudal segment, while suspended from the surface. Their skin becomes the cocoon of the nymph. The latter scarcely change their form, but they assume a rigid consistence, and become incapable of motion. They float upon the water, and their tails frequently form a right angle with the body. The perfect insect issues from a cleft which opens in the second ring. The species are few in number. About half a dozen are found in Britain.

FAMILY XIV.—SYRPHICI.

Antennæ three-jointed; third joint compressed, not ringed, with an apical style, or a dorsal seta at the base: ocelli three: proboscis concealed: abdomen with five segments: onychii two.

a. Antennæ with a terminal style.

Genus Callicera, Meig. Antennæ inserted on a common tubercle, the first joint cylindrical, second of equal length, compressed and dilated at the apex, the third terminating in an acuminated style: abdomen conical: wings incumbent, parallel.

C. *ænea.* Hypostoma yellow and pubescent, having a black line down the middle: thorax pubescent, of a yellow colour, blackish on the back, and marked with three obscure lines: scutellum blackish, the pubescence yellowish white: abdomen shining brassy green, with yellow pubescence, of a conical form in the male, more rounded in the female, and in the former marked with a black nearly triangular spot at the base: legs yellow, the thighs almost entirely black. Males five and a half, females nearly seven lines. *Bibio ænea*, Fab.; *Musca ænea*, Gmelin.

This insect has occurred at Berlin and in the south of France.

Genus Ceria, Fab. Antennæ seated on a common footstalk; the basal joint cylindrical, second and third equal, clavate, compressed, and furnished with an apical style: abdomen cylindrical: wings divaricating?

C. *conopsoides.* Shining black and pubescent: peduncle of the antennæ elongate, and ferruginous; thorax with the shoulders and a small spot near the base of the wings yellow: abdomen with a yellow band on the hinder margin of the second, third, and fourth segments: legs rufous, the thighs brown. Five to six lines *Ceria clavicornis*, Fab.; *Musca conopsoides*, Linn.; Curtis, *B. E.* 186 ♀. Very rare in Britain, but not unfrequent on the continent. There is an English specimen in the British Museum, presented by Dr Leach.

b. Antennæ with a dorsal seta.

Genus Microdon, Illig. Antennæ porrect, the first joint elongate, cylindrical, the third with a naked dorsal seta at the base: scutellum armed with two teeth: wings incumbent, parallel.

M. *apiformis.* The head and thorax are dark brassy, and shining; the hypostoma is covered with bright yellow pubescence, but on the forehead, thorax, and scutellum it is of a fulvous colour: abdomen black, clothed with shining golden-yellow pile, which forms a narrow band at the hinder margin of the first segment, and a broader one on the second, somewhat interrupted in the middle, and covers nearly the whole of the third and fourth segments: wing-scales and halteres white; wings brownish: thighs black, with ferruginous pile, the tibiæ and tarsi entirely ferruginous. Four to five lines. *Musca apiformis*, Degeer, pl. vii. fig. 18–20; *Musca mutabilis*, Linn.; Curtis, *B. E.* 70.

Meigen describes four European species, but the above is the only one known as British. It has been found in the New Forest, and near Lyndhurst, in Hants, but appears to be scarce in the country, although common in France and many other parts of Europe.

Genus Chrysotoxum, Meig. Antennæ inserted on a frontal tubercle, porrect; first joint cylindric, the rest somewhat compressed, equal, the terminal one with a naked dorsal seta at the base: scutellum unarmed: abdomen margined: wings divaricating.

C. *arcuatum.* Hypostoma shining yellow, with a black line down the middle; the forehead of the females black, with two yellow spots; antennæ black: thorax black, with an interrupted yellow line on each side, and two abbreviated cinereous lines on the back: abdomen without hairs, black, and having four arched interrupted bands of golden yellow; belly with four golden-yellow spots; the wings are yellow at the anterior margin, and behind the middle, near the anterior edge, there is a small brown spot. Five and a half lines. *Syrphus arcuatus*, Fab.; *Musca arcuata*, Linn. This insect occurs not unfrequently throughout the south of Scotland and England during the autumn, frequenting various flowers. We have often taken *C. bicinctum* in company with it, on the flowers of *Senecio Jacobæa*, in Roxburghshire. The species have a *waspish* look, from their prevailing hues of black and yellow. They feed on the juices of flowers. Their flight is rapid.

Genus Psarus, Fab. Antennæ inserted on a common peduncle, porrect, the radical joint cylindrical, second elongate and compressed, third oblong and compressed, with a naked seta placed on the middle of the back: wings incumbent, parallel.

P. *abdominalis.* Hypostoma black, with a grey play of colour on the sides; forehead black, with two white spots: thorax black and naked: scutellum semicircular and unarmed: abdomen naked, nearly linear, reddish brown; the base and apex black, sometimes having a black line along the back: wing-scales and halteres white: thighs black; tibiæ and tarsi inclining to brown. Four lines. *Syrphus abdominalis*, Fab.; *Psarus abdominalis*, Lat. Appears to be a rare and little-known species. Specimens found in this country are preserved in the British Museum.

Genus Paragus, Lat. Antennæ with the two basal joints equal, the third elongate, compressed, with a naked dorsal seta before the middle: hypostoma somewhat convex, smooth: abdomen linear, transversely rugose; the hinder metatarsus somewhat thickened: wings parallel, incumbent.

P. *obscurus*. Female. Antennæ proportionally shorter than in most of the other species, and entirely dark brown: eyes pubescent: thorax with a slight grey play of colour, the sides covered with pubescence of a silvery hue: abdomen shining black: legs yellow; the thighs black, with the apex yellow: halteres white. Two and a half lines. Inhabits France and England.

Genus Ascia, Meg. Antennæ with the third joint oblong, compressed, having a naked dorsal seta before the middle: hypostoma impressed, smooth, produced beneath: abdomen contracted at the base: hinder thighs thickened, and spinose beneath: wings incumbent, parallel.

A. *floralis*. Abdomen black, and marked with two yellow fasciæ, which are entire in the male, and interrupted in the female: anterior legs yellow, the tibiæ with a black ring before the apex; the hinder legs black, with a metallic lustre, the thighs yellow at the base, the tibiæ yellow, with a black band in the middle, and the tarsi black: wings hyaline. Two and a half lines.

Found occasionally in gardens and fields in the southern counties of Scotland, and in England.

Genus Sphegina, Meig. Antennæ with the terminal joint orbiculate, compressed, with a naked dorsal seta at the base: hypostoma impressed, smooth: abdomen contracted at the base: hinder thighs clavate, spinose beneath: wings parallel, incumbent. Meig. iii. 193.

S. *nigra*. Hypostoma whitish; antennæ rufous-brown: thorax and abdomen shining black, the former with a greenish tint: halteres yellowish white: the four anterior legs pale yellow; thighs of the hinder pair black, yellow at the base; the tibiæ with two brown bands; tarsi black. Three to three and a half lines. Two species only belong to this genus, both of which are to be found in Britain. Mr Duncan took a few examples of the above in the neighbourhood of Edinburgh in the summer of 1830. The other species, *S. clunipes* (Meig. pl. xxviii. f. 5) is of more frequent occurrence.

Genus Baccha, Fab. Antennæ with the third joint sub-orbicular, compressed, having a naked dorsal seta at the base: hypostoma tuberculated: abdomen elongate, attenuated before, and clavate behind: legs simple: wings parallel and incumbent.

B. *nigripennis*. Antennæ brown: thorax dark brassy, the abdomen inclining to golden green, and flat behind; at the base of the third segment there is a scarcely perceptible yellow spot on each side, and a yellow band on the fourth: anterior legs yellow; the hinder ones brownish, with the base of the thighs yellow: wings blackish. Three lines. Found in Austria by M. Megerle. It likewise occurs in Britain, along with six other species—nearly the whole that the genus contains.

Genus Eumerus, Meig. Antennæ with the third joint orbicular, compressed, and having a naked dorsal seta before the middle: hypostoma sub-convex, villose, smooth: hinder thighs thickened, and spinose beneath: wings incumbent, parallel.

E. *grandis*. Hypostoma covered with whitish pubescence; forehead of the males similar, that of the female black, with white pubescence under the eyes: antennæ dark brown: thorax dark brassy, with two whitish lines anteriorly, the sides somewhat shining: abdomen black, the sides testaceous, and adorned with three pair of crescent-shaped spots: legs dark metallic green, the tibiæ and tarsi with ferruginous pubescence: halteres brown: wing-scales white; wings grey. Five lines. Meig. *Zw.* iii. pl. xxviii. f. 18. Five species of Eumeri are found in this country: *E. ruficornis*, *ornatus*, *strigatus*, *funeralis*, and *silene*. The one described above occurs on the continent.

Genus Xylota, Meig. Antennæ inserted on a frontal tubercle, nutant, the third joint sub-orbicular, compressed, with a naked dorsal seta at the base: hypostoma impressed, blunt below, smooth, or somewhat tuberculated: hinder thighs thickened, and spinose beneath: wings incumbent, parallel.

X. *sylvarum*. Hypostoma yellowish white, and finely pubescent, the forehead similar in the male, but in the female shining black, with two white spots anteriorly: antennæ brown: thorax dark metallic green, with a grey spot on each shoulder; the pubescence on the sides golden yellow: scutellum dark green: abdomen black, the two first segments thinly clothed with golden pubescence; similar pubescence covers the base and sides of the third, leaving a triangular black spot behind, and the fourth segment is entirely covered with it; fifth segment minute and shining black: wing-scales and halteres yellowish white: wings brownish, with a ferruginous stigma: legs ferruginous, the thighs and two last tarsal joints black; hinder thighs club-shaped, and armed with small prickles; tibiæ crooked, and having a brown play of colour behind. Six lines. *Musca sylvarum*, Linn.; *Syrphus sylvarum*, Fab.; *Milesia sylvarum*, Lat. Found occasionally in various parts of the continent. We have taken single specimens near Edinburgh, and in the neighbourhood of Jedburgh. *X. segnis*, and *pipiens*, are comparatively common in England and the south of Scotland. The former is often plentiful at Roslyn. The larva of this genus, described by Degeer, was found in the dung of horses.

Genus Milesia, Fab. Antennæ inserted on a frontal tubercle, the third joint lenticular, with a naked dorsal seta at the base; hypostoma impressed, smooth, or slightly tuberculated; legs simple, the hinder tibiæ compressed; wings incumbent, parallel, the intermediate transverse nerve oblique.

M. *speciosa*. Hypostoma and forehead ferruginous, with a yellowish-white play of colour on the sides; the crown black: antennæ ferruginous: thorax dark brassy green, finely pubescent, blackish on the sides, and yellow on the shoulders: abdomen dark brassy, cylindrical, and finely pubescent; having a line along the back, and the hinder margin of the segments covered with shining golden-yellow pubescence, and before this yellow edging there is a transverse band of black: wing-scales white: halteres bright yellow: wings brownish yellow along the anterior margin, but before the apex this colour passes into brown: thighs dark brown, with a ferruginous spot at the apex; tibiæ and tarsi ferruginous. Seven lines. Found, according to Meigen, near Paris, and likewise in Austria and Italy. "It is now several years," says Mr Curtis, who has given a beautiful representation of this insect in his *Brit. Entom.* fol. 34, "since this fine and rare insect was discovered in the New Forest by Mr D. Bydder, and the beginning of June of the present year (1824) I took four near Brockenhurst: they appear to delight in settling in the thickest parts of the Forest, where a partial shadow is thrown by the surrounding foliage upon the trunks of trees, or the flat surface remaining when they have been felled."

Genus Pipiza, Meig. Antennæ nutant, the third joint ovate and compressed, having a naked dorsal seta at the base: hypostoma smooth: hinder thighs somewhat thickened: abdomen oblong-elliptical: wings parallel, incumbent.

P. *Artemis.* Black, with whitish hair: the second segment of the abdomen with a lunate fascia of a red colour: thighs black, tibiæ ferruginous anteriorly, brown behind; tarsi ferruginous: halteres bright yellow: wing-scales white; outer half of the wings brown, the colour becoming paler at the apex: belly black, yellow anteriorly. Three lines. Inhabits Austria and England. There are fifteen British species of this genus, and twenty-nine are indigenous to Europe.

Genus Psilota, Meig. Antennæ nutant, the terminal joint oblong-ovate, with a naked dorsal seta at the base: hypostoma impressed, truncated beneath: eyes hirsute: wings incumbent, parallel.

P. *anthracina.* Hypostoma and forehead bluish black; the body of a similar colour, and covered with very short pubescence; abdomen oval: legs black, the thighs all straight; the tarsi with fine ferruginous pubescence; the hinder legs somewhat elongate, and the tibiæ a little bent: wing-scales and halteres white; wings hyaline, somewhat yellowish at the base, and the stigma bright yellow. Three lines. Meig. *Zw.* iii. pl. xxix. f. 20. Found in Germany and Britain.

Genus Rhingia, Fab. Antennæ porrect, nutant, the third joint lenticular, the base with a naked dorsal seta: hypostoma somewhat impressed, elongate beneath, conical: wings incumbent, parallel. Meig. iii. 257; Lat. *Gen. Crust.* iv. 320.

R. *rostrata.* Hypostoma and rostrum ferruginous, shining, the latter brown at the tip; antennæ ferruginous; forehead of the females grey, with a dark streak: thorax grey, with three black-brown lines; scutellum shining, brownish yellow: abdomen ferruginous, the basal segment sometimes blackish, and a longitudinal brown line on the second: legs ferruginous, the hinder tarsi brownish: wing-scale and halteres light yellow: wings somewhat greyish, yellowish at the anterior margin. Four lines. Meig. iii. 258. *Conops rostrata*, Linn., &c. Common throughout the country. *R. campestris* (Curtis, *B. E.* pl. clxxxii.), which differs from the above chiefly in having the incisures of the abdomen, and a longitudinal dorsal line, of a black colour, is likewise of frequent occurrence, and is probably not specifically distinct. The name of a third species, *R. monostigma*, has been recently published, but we are unacquainted with its characters and history. We have but a slight knowledge of the metamorphoses of these insects. Indeed all that is yet known is inferred from the fact of Réaumur having found *Rhingia rostrata* in the perfect state in a sand-box (*poudrier*) in which he had previously enclosed some cow-dung containing unknown larvæ. The perfect insects occur in gardens and meadows. The species are by no means numerous.

Genus Brachyopa, Hoff. Antennæ inserted on a frontal tubercle, nutant, the terminal joint lenticular, and having a hirsute dorsal seta at the base: hypostoma impressed and elongate beneath, truncated: wings incumbent, parallel, one half longer than the abdomen.

B. *bicolor.* Hypostoma, antennæ, and forehead (of the males) ferruginous, with a white play of colour; forehead of the females grey, with a yellow spot anteriorly: thorax dark grey or lead colour, with three brown lines, of which the central one is double: scutellum rust-brown: abdomen ferruginous, with a black dorsal line on the second segment, which however is sometimes wanting: legs ferruginous, with dark-brown tarsi: wing-scales white: halteres bright yellow: wings unspotted, slightly obscured with brown. Three lines. *Rhingia bicolor,* Fallen. The insects of this genus are found on flowers, but seem to be in general rare. The above, and another species named *B. conica*, are said to have occurred in England.

Genus Chrysogaster, Meig. Antennæ nutant, the third joint compressed, orbiculate, or oblong, having a naked dorsal seta at the base: forehead of the female crenated on both sides: abdomen depressed: wings parallel, incumbent.

C. *ænea.* Shining brassy, except the apex of the abdomen, which is dull black; the belly dark green: antennæ testaceous: wings hyaline, partly of a yellowish-brown colour, with a ferruginous stigma. Three lines. Inhabits Austria and Britain, but seems everywhere rare.

Genus Syrphus, Fab. (Plate CCXXXVIII. figs. 17 and 17 *a.*) Antennæ porrect, nutant, three-jointed; the third joint orbicular or oval, compressed, with a pubescent dorsal seta at the base: hypostoma tuberculated: feet simple, slender: wings incumbent, parallel, the ordinary transverse nerve nearly perpendicular.

S. *Lucorum.* Hypostoma white, with a shining black line down the middle; forehead whitish, having a black spot over the antennæ, and a brown line in the females: antennæ black, with a very finely pubescent seta: thorax black, with reddish-yellow pile; scutellum rufous: abdomen having the first segment whitish, with pubescence of the same colour, the male with a wide dark-coloured vitta; third segment deep black; fourth black, with whitish pubescence and somewhat glossy, especially on the sides: legs dark brown, the base of the tibiæ whitish: halteres and wing-scales brown; wings hyaline, having a dark-brown vitta in the middle of the anterior margin extending half way across. Five lines. Meig. iii. 313, pl. xxx. f. 27. *Musca lucorum*, Linn. Not unfrequent on umbelliferous plants in woods throughout the country. The genus *Syrphus*, as characterized by Meigen, comprehends nearly 100 species, of which upwards of one half, besides a considerable number of others recently discovered, are to be found in Britain. The dissimilarity in form and structure which prevails among many of these insects, has led to their distribution, by later writers, into three generic groups, distinguished by the names *Cheilosia, Scæva, Syrphus;* and they appear to be susceptible of still further subdivision. As the English species are comparatively well known, it may be interesting to mention such as we have ascertained to inhabit Scotland: *S. ostraceus* (frequent), *variabilis, lunulatus, Pyrastri, seleniticus, Ribesii* (common), *balteatus* (common), *cinctus, decorus, umbellatarum, tæniatus, mellitargus, Rosarum, Ocymi, granditarsus* (three last near Edinburgh, not common). The larvæ of the Syrphi prey upon Aphides. Their form is that of an elongated cone. Their segments are very retractile.

Genus Pelecocera, Hoff. Antennæ porrect, the third joint somewhat patelliform, the apex furnished with a thick, short, three-jointed seta: hypostoma arched beneath.

P. *tricincta.* Hypostoma white, with a shining black vitta: thorax black, shining, the shoulders white, and the sides before the base of the wings marked with a white streak: scutellum shining black; abdomen likewise black, with a broad ferruginous band at the base of the second, third, and fourth segments: legs reddish yellow, the hinder pair with a brown ring on the thighs and tibiæ: wing-scales and halteres white: wings somewhat brownish, with a ferruginous stigma. Three lines. Found in some parts of the continent, but everywhere rare.

Genus Sericomyia, Lat. Antennæ porrect, nutant, the third joint patelliform; the base with a plumose dorsal seta: hypostoma descending, tuberculated: wings parallel, incumbent, hirsute.

S. *borealis.* Hypostoma ochreous, with a black line; antennæ dark brown; forehead of the males yellow, of the females black brown: thorax black, with a tuft of whitish pubescence on each shoulder, and golden-yellow pubescence on each side before the base of the wing: scutellum blackish brown: abdomen black, with four ochreous bands, the first, and sometimes the second also, somewhat interrupted; belly dull ochreous, brown at the base: legs rufous, base of the thighs black: wing-scales yellow: halteres brown: wings hyaline, with the anterior margin yellowish, and sometimes with a pale-brown tinge before the apex. Seven lines. *Syrphus borealis*, Fallen; *Musca lappona*, Degeer. Abundant in some parts of the south of Scotland during the autumnal months, and frequently seen on the flowers of *Senecio Jacobæa*, in company with numerous species of the genus *Eristalis.* Its appropriate locality seems to be elevated pasture lands, and the sides and summits of hills. In the latter situation we have occasionally heard it, in fine weather, emit a peculiarly shrill and stridulent note, which is sufficiently loud to be heard at a considerable distance. A nearly allied species, *S. lappona*, Linn., occurs among the Pentland Hills, near Edinburgh.

GENUS TROPIDIA, Meig. Antennæ nutant, third joint patelliform, with a naked dorsal seta: hypostoma carinated, smooth: hinder thighs thickened, with a single tooth at the apex beneath: wings parallel, incumbent, hirsute.

T. *fasciata.* Hypostoma greyish white, with a black longitudinal line, and covered with fine silky hairs; antennæ rufous: thorax with yellow pubescence, of a dark green, somewhat metallic, with two whitish abbreviated lines on the back, and a spot on each shoulder: abdomen with ferruginous pubescence, of a dark brown, and having a rufous interrupted band on the second, third, and fourth segments: thighs of the anterior legs blackish, the apex rufescent, the tibiæ and tarsi rufous, with a brown apex: hinder thighs blackish, the tibiæ crooked, reddish at the base, the other parts, as well as the tarsi, brown: halteres and wing-scales white: wings hyaline. Four lines. Found in some parts of the continent on *Achillæa ptarmica*, in the neighbourhood of Paris, and in Austria. The only other species described by Meigen, *T. milesiformis*, has been found in Britain, along with another, named *T. rufomaculata* (Curtis), which does not appear to be known to continental naturalists.

GENUS MERODON, Fab. Antennæ nutant, the terminal joint oblong or elliptical, compressed, with a naked dorsal seta at the base; hypostoma smooth and villose: hinder thighs thickened, with a single tooth at the apex beneath: wings incumbent, parallel, hirsute.

M. *equestris.* Male. Hypostoma and forehead with greyish white pubescence; antennæ black: thorax anteriorly dark brassy, with ferruginous pile, shining black behind, with pile of the same colour: scutellum and abdomen coloured and clothed like the anterior part of the thorax: legs black, the anterior tibiæ and tarsi with ferruginous silky hairs; the hinder tibiæ with a tubercle on the inner side behind the middle, and a hooked spine at the end: halteres brown: wings nearly hyaline. Six lines. *Syrphus equestris*, Fab. Réaumur, *Ins.* iv. tab. xxxiv. fig. 9, 10. This species has occurred in Italy and near Paris. *M. clavipes* is the only British species known. It is figured and described in Curtis' *B. E.* fol. xcviii.

GENUS HELOPHILUS, Meig. Antennæ porrect, nutant, the terminal joint patelliform, the base with a naked dorsal seta: hypostoma descending, gibbous beneath: eyes naked: hinder thighs thickened, unarmed: wings divaricating, hirsute.

H. *pendulus.* Hypostoma yellowish white, with a shining black vitta in both sexes; forehead whitish yellow, the crown dark brown, and a small black spot over the antennæ; the latter dark brown, with a yellow seta: thorax straw colour, with three black vittæ: scutellum shining brownish yellow: abdomen deep black, with three unequal interrupted yellow bands: the belly pale anteriorly, the three last segments black, with white incisures: wing-scales and halteres yellow; anterior legs rufous, nearly the whole of the thighs and the tarsi brown; hinder legs dark brown, the apex of the thigh and base of the tibiæ more or less yellow. Five lines. *Syrphus pendulus*, Fab.; *Musca pendula*, Linn.; *Elophilus pendulus*, Lat Everywhere common. The species of this genus do not greatly differ from those of *Eristalis.* They are generally less hairy. Several exhibit the aspect of garden bees, as well as of other Hymenoptera. The larvæ, known under the name of rat-tailed worms (*vers à queue de rats*, Réaumur),[1] are remarkable for the great length and singular uses of their caudal extremity. It serves as a respiratory organ. The insect lies at the bottom of stagnant waters, generally concealed in the mud; but the point of its attenuated tail is meanwhile in contact with the surface. Réaumur found, by increasing the depth of water, that the larva could extend its respiratory tube to the height of five inches. After that, however, it was seen to leave the mud, and ascend the side of the vessel in which it was contained, that it might attain to the surface with greater ease. The tail seems composed of two parts, one of which slips into the other like the portions of a telescope. They are composed of annular fibres, and when these are contracted, each tube is greatly increased in length.

GENUS MALLOTA, Meig. Antennæ nutant, third joint nearly four-angled, compressed, with a naked dorsal seta in the middle: hypostoma descending, gibbous: wings divaricating, hirsute.

M. *megilliformis.* Male. Hypostoma black, thickly covered with silken hairs of a pearl-grey colour, and having a naked shining black vitta; forehead black, pearly on the sides beneath; the hinder part of the head with ferruginous pile; antennæ black, the third joint with a white seta: thorax and abdomen dark green, thickly clothed with ferruginous hair; belly and legs black; wing-scales ferruginous; halteres also ferruginous, with the knob brown: wings nearly hyaline, with brown nervures. Six lines. Rare: The females have not been described. The genus contains only three species, none of which appear to be British.

GENUS ERISTALIS, Fab. Antennæ porrect, nutant, three-jointed; the third joint patelliform, with a plumose or naked seta at the base: hypostoma elongate, tuberculated: legs simple: wings spreading, naked (in the greater number of species).

E. *intricarius.* Male. Hypostoma and forehead black, with yellowish-white hair; antennæ black at the base, the third joint rufous, with a plumose seta of the same colour at the base: thorax black, thickly clothed with reddish-yellow hair; scutellum yellow: abdomen black, with ferruginous lateral spots, and clothed anteriorly with ferruginous hair, which on the hinder parts passes into a whitish-yellow colour: wing-scales blackish: wings hyaline, the central cross nerve more or less distinctly margined with brown: legs black, the apex of the thighs and basal half of the tibiæ white. Six lines. Meig. iii. 391. *Syrphus intricarius*, Fab.; *Musca intricaria.* Linn. Of frequent occurrence during summer on flowers and plants. Several species of this extensive genus are very common in this country, particularly *E. tenax, similis, horticola*, &c. About a score inhabit Britain. The larva of *E. narcissi* (which inhabits the bulb of the plant from which it derives its name) is figured and described by Réaumur.[1]

---

[1] *Mémoires*, t. iv. p. 442.

GENUS VOLUCELLA, Geoff. Antennæ decumbent, the third joint elongate, compressed, with a long plumose dorsal seta at the base: hypostoma impressed above, elongate beneath, conical, gibbous: wings divaricating. Meig. iii. 401; Lat. *Gen. Crust.* iv. 322.

V. *pellucens.* Hypostoma, forehead, and antennæ shining ferruginous, the latter with a black plume: thorax shining black, bristly: scutellum testaceous brown, sometimes black,[2] bristly: abdomen pubescent, shining black, the second segment yellowish white, pellucid, having a central line of black in the males, but usually uninterrupted in the females, except by a very faint black line; belly like the back, except the anterior part of the third segment, which is likewise transparent: legs black: wing-scales yellowish: halteres with a blackish stalk, the knob white: wings yellowish at the base, with ochreous veins, the rest greyish, with brown veins. Seven lines. Meig. iii. 405. *Musca pellucens*, Linn. An insect of not unfrequent occurrence in Britain during the summer months, frequenting flowers in sheltered situations exposed to the sun. In the summer of 1829 it appeared in unusual abundance in the fields adjoining Duddingston wood, near Edinburgh. All the other species belonging to the genus (as now restricted) are to be found in Britain, with the exception of *V. zonaria* (Meig. iii. pl. xxxii. f. 27). The most common in Scotland next to the species described is *V. plumata*, which is found occasionally throughout the southern counties. *V. bombylans* appears to be considerably scarcer; the only examples which we have met with were from Dumfriesshire and East Lothian. The larvæ of these insects inhabit the nests of wasps and bees, and live at the expense of the proper owners. Réaumur has detailed their history at great length, and in a very interesting manner. "Lepelletier de Saint Fargeau a eu occasion d'observer que les volucelles de diverses espèces s'accouplent trés-bien ensemble; il a lu un Mémoire à ce sujet à l'Académie des Sciences."[3]

FAMILY XV.—PLATYPEZINÆ.

Antennæ porrect, two or three-jointed, with a naked apical seta: proboscis concealed; thorax without a transverse suture: abdomen with six segments: wings incumbent: the small cross nerve of the middle bent towards the base: halteres naked.

GENUS CYRTOMA, Meig. Antennæ approximating, two-jointed, first joint small, cylindric; second elongate, conic, compressed, the apex with a two-jointed style: proboscis subporrect: hinder legs elongate: wings incumbent, parallel. Meig. iv. 1.

C. *nigra.* Black; halteres yellow; the legs brown; the hinder tibiæ club-shaped, the lowest joint of the tarsi thickened; wings somewhat brownish. Two lines. Found in Germany and elsewhere occasionally. This genus contains three species, none of which are known to inhabit Britain.

GENUS PLATYPEZA, Meig.; name derived from πλατυς, *broad*, and πεζα, *the foot.* Antennæ straight, approximating, three-jointed, the lower joints sub-cylindric, third ovate, compressed, the apex with a three-jointed naked seta: proboscis concealed: hinder feet thickest, tarsi dilated, the joints nearly equal: wings incumbent, parallel.

P. *boletina.* Male. Velvet black; abdomen with greyish-black bands: legs brown: halteres black brown: wings hyaline.

Female. Clear ash-grey, abdomen with a narrow deep black cross band, somewhat widened in the middle, before the incisures; the first segment without a band: halteres and legs bright yellow: wings hyaline. One and a half line. Fallen. Occurs in Germany and England, rare.

GENUS CALLOMYIA, Meig. (Plate CCXXXVIII. figs. 18 and 18 *a.*) Generic name from καλος, *beautiful*, and μυια, *a fly.* Antennæ straight, three-jointed; the lower joints sub-cylindric, third compressed, acute; the terminal seta elongate, three-jointed: proboscis concealed: hinder legs elongate, thick, the metatarsus elongate: wings incumbent, parallel.

C. *amœna.* Male. Body velvet black: halteres rufous: fore legs honey-yellow, the thighs blackish brown: hinder legs entirely black brown: wings hyaline.

Female. Hypostoma and forehead bright blue: thorax bright blue on the sides, with a silvery lustre: this colour extends forwards along the thorax in the form of a bow, and before the scutellum there is likewise a silvery band: scutellum black: abdomen with the three first segments orange yellow, the fourth and sixth deep black, the fifth silvery blue, with a black line on the middle; fore legs rufous; hinder legs black, with rufescent thighs: halteres rufous: wings hyaline. Two lines. Meig. *Zw.* iv. pl. i. f. 13. This species has been recently taken in England.

FAMILY XVI.—MEGACEPHALI.

Antennæ three-jointed; the third joint deflexed, with an erect seta at the base: hypostoma linear, narrow: proboscis concealed: abdomen consisting of six segments: wings incumbent; the short transverse nervure in the middle: halteres naked.

GENUS PIPUNCULUS, Lat. (Plate CCXXXVIII. figs. 19 and 19 *a.*) Antennæ triarticulate; first joint minute, second cup-shaped, third deflexed, acute, compressed, with an erect naked seta at the base: hypostoma narrow, linear: proboscis concealed: wings incumbent, parallel. Meig. *Zw.* iv. 18, pl. xxxiii. f. 15–24.

P. *spurius.* Deep velvet black, the apex of the abdomen somewhat shining: hypostoma silver white, changing, with a play of colour, into black: forehead very narrow, black, silver white above the antennæ: the latter, together with the legs, black: wings brownish, with a dark-coloured stigma. One line. Meig. *Zw.* iv. pl. xxxiii. f. 24. Occurs in England, but is rare.

FAMILY XVII.—DOLICHOPODES.

Antennæ porrect, three jointed: the third joint flat, with an apical or dorsal seta: hypostoma linear: proboscis somewhat exserted, with compressed incumbent palpi: thorax without a transverse suture: abdomen consisting of six segments: wings incumbent; the short transverse nerve bent towards the base: halteres naked.

GENUS RHAPHIUM, Meig. Antennæ approximating, the third elongate, compressed, with a two-jointed style at the apex: eyes separated: wings incumbent, parallel.

---

[1] *Mémoire*, t. iv. p. 499, and pl. xxxiv.

[2] The scutellum is usually ferruginous when the insect issues from the chrysalis, but becomes darker as it advances to maturity, till it ultimately acquire the colour of the thorax.

[3] *Diction. Class. d'Hist. Nat.* t. xvi. p. 631.

R. *vitripenne.* Hypostoma bluish white; forehead shining steel blue: antennæ black, slender, those of the male as long as the abdomen, those of the female much shorter; the body dark metallic green, legs black, the anterior tibiæ brown; halteres white: wings hyaline. Three lines. Meig. *Zw.* iv. pl. xxxiii. f. 4. Four species of this genus, nearly half the number known, have been found in Britain. The species described occurs on the continent.

Genus Diaphorus, Meig. Antennæ with the third joint patelliform, having a villose dorsal seta: eyes meeting on the forehead; abdomen of the male with two filiform appendages on the under side of the apex: wings incumbent, parallel. Meig. *Zw.* iv. pl. xxxiv. f. 6–9.

D. *flavocinctus.* Hypostoma white; antennæ black: body black, with greenish reflections; the second segment of the abdomen, and sometimes the base of the third, ferruginous, transparent: anterior legs rufous, with blackish thighs, rufescent at the apex on the under side: middle pair of legs rufous, the basal half of the thighs black: hinder legs black, the upper half of the tibiæ rufous: halteres white: wings reddish brown. One and a half line. Meig. *Zw.* iv. pl. xxxiv. f. 8. Inhabits England, but is not common.

Genus Psilopus, Meg. Antennæ with the third joint patelliform, villose; furnished with an inclined villose dorsal seta before the apex: eyes separated: wings incumbent, parallel, the transverse nerve at the apex curved.

P. *platypterus.* Male. Head white: antennæ pale yellow; the third joint brown: palpi white: thorax cinereous-green, with a faint metallic lustre: abdomen brassy, the apical segment blackish: legs long, pale yellow: halteres yellow: wings very broad, hyaline.

Female. Hypostoma somewhat wider than in the male: legs pale yellow, with brownish tarsi. Two and a half lines; the females rather less. This and seven other species of Psilopi are found in Britain, but none of them appear to be frequent.
